THE AMERICAN PSYCHIATRIC ASSOCIATION

OFFICERS 1960-1961

President: ROBERT H. FELIX
Vice President: D. GRIFFITH MCKERRACHER
Secretary: C. H. HARDIN BRANCH

President-Elect: WALTER E. BARTON
Vice President: R. W. WAGGONER
Treasurer: ADDISON M. DUVAL

COUNCILLORS

For 3 years
 WILLIAM MALAMUD
 DANIEL BLAIN
 DAVID A. BOYD, JR.
 M. RALPH KAUFMAN

For 2 years
 FRANCIS J. GERTY
 PAUL HOCH
 CALVIN DRAYER
 ALDWYN STOKES

For 1 year
 HARRY C. SOLOMON
 LAWRENCE C. KOLB
 DANA L. FARNSWORTH
 ROBERT T. MORSE

EXECUTIVE COMMITTEE

ROBERT H. FELIX
 WALTER E. BARTON
 C. H. HARDIN BRANCH

ADDISON M. DUVAL
 WILLIAM MALAMUD
 ALDWYN B. STOKES

Ex-Officio
 D. GRIFFITH MCKERRACHER
 R. W. WAGGONER

ASSEMBLY OF DISTRICT BRANCHES

JOHN R. SAUNDERS
 (Speaker)

EDWARD G. BILLINGS
 (Speaker Elect)

LESTER E. SHAPIRO
 (Recorder)

MEDICAL DIRECTOR

MATHEW ROSS, 1700-18th Street, N. W., Washington 9, D. C.

EXECUTIVE ASSISTANT

AUSTIN M. DAVIES, 1270 Avenue of the Americas, New York 20, New York

CHAIRMEN OF COMMITTEES

CONSTITUTIONAL COMMITTEES

Arrangements
 HUGH T. CARMICHAEL
Board of Tellers
 EVELYN IVEY

SPECIAL COMMITTEE
Certification of Mental Hospital Administrators
 WINFRED OVERHOLSER

AMERICAN JOURNAL OF PSYCHIATRY

INFORMATION FOR CONTRIBUTORS

Manuscripts—The *original* manuscripts of papers read at the annual meetings of the Association should be deposited with the Secretary during the meetings, or sent to the New York office promptly afterwards. Do not deposit carbon copies.

Papers read at the annual meetings become the property of the Association. Not all papers read, however, can be published in the JOURNAL, and authors wishing to publish in other vehicles will first secure from the Editor the release of their manuscripts.

Papers will not be accepted for the annual program if they have been previously read at other meetings or if they have been already published.

Papers contributed during the year (not on the annual program) should be sent to the Editor, Dr. Clarence B. Farrar, 200 St. Clair Avenue, West, Toronto 7, Ontario, Canada.

Style—Manuscripts should be typewritten, double spaced, on one side of the paper. They must be prepared in conformity with the general style of The American Journal of Psychiatry. Retain a carbon copy of manuscript and duplicates of tables, figures, etc., for use should the originals be lost in the mails.

Multiple Authorship—The number of names listed as authors should be kept to a minimum, others collaborating being shown in a footnote.

Illustrations—Authors will be asked to meet printer's costs of reproducing illustrative material. Copy for illustrations cannot be accepted unless properly prepared for reproductions. Wherever possible, drawings and charts should be made with India ink for photographic reproduction as zinc etchings. Photographs for halftone reproduction should be glossy prints. Illustrations should be as small as possible without sacrificing important detail. Redrawing or preparing illustrations to make them suitable for photographic reproduction will be charged to author.

Authors' Corrections in Proofs—Corrections, additions or deletions made by authors are to be charged to them. These alterations are charged on a time basis at the rate of \$7.00 per hour. Proper editing of original manuscript is important to avoid the expense of correction.

Tables—Tables should be typed on separate sheets. Tables are much more expensive to set than text material and should be used only where necessary to clarify important points. Authors will be asked to defray cost of excessive tabular material.

References—References should be assembled according to author in a terminal bibliography, referred to in text by numbers in parentheses. Bibliographical material should be typed in accordance with the following style for journals and books respectively:

1. Vander Veer, A. H., and Reese, H. H.: *Am. J. Psychiat.*, 95 : 271, Sept. 1938.
2. Hess, W. R.: *Diencephalon*. New York: Grune & Stratton, 1954.

Abbreviations should conform to the style used in the Quarterly Cumulative Index Medicus.

The American Journal of Psychiatry, formerly The American Journal of Insanity, the official organ of The American Psychiatric Association, was founded in 1844. It is published monthly, the volumes beginning with the July number.

Articles appearing in this Journal do not necessarily reflect the official attitude of The American Psychiatric Association or of the Editorial Board.

The subscription rates are \$12.00 to the volume: Canadian subscriptions \$12.50; foreign subscriptions, \$13.00, including postage. Rates to medical students, junior and senior internes, residents in training during their first, second, or third training year, and also to graduate students in psychology, psychiatric social work, and psychiatric nursing, \$5.00 (Canada \$5.50). Single issues, \$1.50. Copyright 1961 by The American Psychiatric Association.

Office of Publication, 10 Allen St., P.O. Box 832, Hanover, N. H.

Business communications, remittances and Subscriptions should be addressed to The American Psychiatric Association, 10 Allen St., P.O. Box 832, Hanover, N. H., or to 1270 Avenue of the Americas, New York 20, N. Y.

Editorial communications, books for review, and exchanges should be addressed to the Editor, Dr. Clarence B. Farrar, 200 St. Clair Avenue, West, Toronto 7, Ontario, Canada.

Second class postage paid at Hanover, New Hampshire.

CONTENTS OF VOLUME 117

JULY, 1960

PRESIDENTIAL ADDRESS. William Malamud . . .	1	BASIC CRITERIA OF SCHIZOPHRENIA. Howard N. Cooper . . .	66
DR. WILLIAM MALAMUD. Bernard J. Alpers . . .	11	CLINICAL NOTES :	
CHILD PSYCHIATRY: RETROSPECT AND PROSPECT. Leo Kanner . . .	15	Methoxypromazine in Chronic Schizophrenia. Max Apfeldorf, Hans G. Bauer, and Thomas H. McGavack . . .	72
SOME PROBLEMS OF DOSE VARIATION IN THE USE OF TRANQUILIZING DRUGS. Sidney Malitz, and Bernard Wilkely . . .	23	Adjuvant Therapy with Isocarboxazid. Stanley R. Dean . . .	73
BACKGROUND FACTORS AND SYMPTOM PRESENTATION IN A CHILD GUIDANCE CLINIC. Frank G. Buckman, and Marvin Reznikoff . . .	30	Rapid Intensive Treatment of Impending Relapse. Herman C. Denber, and Paul Rajotte . . .	74
A CHILDREN'S UNIT IN A STATE HOSPITAL. Nicholas E. Stratas, and K. T. Schmidt . . .	34	A Comparative Trial of ECT and Tofranil. H. Merskey, E. M. Bruce, N. Crone, G. FitzPatrick, S. J. Frewin, A. Gillis, C. F. Lascelles, and L. J. Levene . . .	76
CASTE AND MENTAL HOSPITAL ADMISSIONS IN MYSORE STATE, INDIA. J. Hoenig, and Uma Sreenivasan . . .	37	Unrelatedness of Mecholyl Chloride Autonomic Reaction Indices. David Pearl, and Harry Vanderkamp . . .	77
A PSYCHIATRIC CENSUS OF THE SOUTH PACIFIC. Eric Berne . . .	44	CASE REPORTS :	
MURDER WITHOUT APPARENT MOTIVE: A STUDY IN PERSONALITY DISORGANIZATION. Joseph Satten, Karl A. Menninger, Irwin Rosen, and Martin Mayman . . .	48	Gilles de la Tourette's Disease. Jerome M. Schneck . . .	78
THE HYPOTHESIS OF RECIPROCAL COMPLEMENTARITY. A. H. Hobbs . . .	54	HISTORICAL NOTES :	
SOME PATHOLOGICAL FINDINGS IN SCHIZOPHRENICS. Donald L. Howie . . .	59	Pietro Pisani (1760-1837): A Precursor of Modern Mental Hospital Treatment. George Mora . . .	79
URINARY EXCRETION OF TRYPTOPHAN METABOLITES BY SCHIZOPHRENIC INDIVIDUALS. F. Christine Brown, J. B. White, Jr., and J. K. Kennedy . . .	63	COMMENTS :	
PROBLEMS IN THE APPLICATION OF THE		Annual Meeting, 1960 . . .	82
		Editorial Board Changes . . .	82
		CORRESPONDENCE :	
		Dynamic Orientation . . .	85
		Marriage Annulment . . .	85
		NEWS AND NOTES . . .	86
		BOOK REVIEWS . . .	89

AUGUST, 1960

TREATMENT OF SCHIZOPHRENIC REACTIONS WITH PHENOTHIAZINE DERIVATIVES: A COMPARATIVE STUDY OF CHLORPROMAZINE, TRIFLUOPROMAZINE, MEPHAZINE, PROCHLORPERAZINE, PERPHENAZINE AND PHENOBARBITAL. J. F. Casey, Julian J. Lasky, C. James Klett, and Leo E. Hollister . . .	97	THE OPERATIONAL MATRIX OF PSYCHIATRIC PRACTICE. II. VARIABILITY IN PSYCHIATRIC IMPRESSIONS AND THE PROJECTION HYPOTHESIS. John H. Rohrer, and George N. Raines . . .	133
MODES OF ABSTRACT THINKING AND PSYCHOSIS. N. McConaghy . . .	106	AN EXPERIENCE OF PSYCHIATRY IN BRITAIN AND AMERICA. Henry R. Rollin . . .	140
SOCIOPSYCHOLOGICAL CHARACTERISTICS OF RESIDENT PSYCHIATRISTS AND THEIR USE OF DRUG THERAPY. Gerald L. Klerman, Myron R. Sharaf, Mathilda Holzman, and Daniel J. Levinson . . .	111	MOTOR FUNCTION IN MENTATION; IMAGERY AND HALLUCINATION; THE INDEPENDENCE OF THE HIGHEST CEREBRAL CENTERS. Max Levin . . .	142
HAZARDS OF DRUG EVALUATION: TRIALS OF 84 NON-APPROVED DRUGS. J. A. Smith, and Cecil L. Wittson . . .	118	THE USE OF RAUWOLFIA FOR THE TREATMENT OF PSYCHOSES BY NIGERIAN NATIVE DOCTORS. Raymond Prince . . .	147
THE RELATIONSHIP OF MENTAL AND PHYSICAL STATUS IN INSTITUTIONALIZED AGED PERSONS. A. I. Goldfarb, R. L. Kahn, M. Pollack, and I. E. Gerber . . .	120	CLINICAL NOTES :	
TUBERCULOSIS IN STATE MENTAL HOSPITALS. James W. MacDonald . . .	125	Tranlycypromine in Depression: A Clinical Report. Henry V. Agin . . .	150
		Memory Changes with MAO Inhibitor Therapy. Leon D. Hankoff, and Boris Heller . . .	151
		Persistent Muscular Restlessness after Phenothiazine Treatment: Report of Three Cases. Walter Krug . . .	152
		On the Measurement of Aerenochrome in Blood. I. Munkvad, and Axel Randrup . . .	153

The Epinephrine-Mecholyl Test Applied to a State Hospital Population. <i>Pandelis K. Pandelidis, and Robert D. Busiek</i>	154	HISTORICAL NOTES : I Remember Stewart Paton. <i>Clarence B. Farrar</i>	160
Mood Elevating Effects of Chlorphenoxamine HCl. <i>Gerald H. Rozan, and David M. Eitenberg</i>	155	COMMENTS : 1960 Campaign for Polio Protection	163
Serum Protein Participation and New Drug Evaluation. <i>J. R. Shawyer, and Stanley M. Tarnowski</i>	156	The Social Problem of Epilepsy in Peru	163
Clinical Observations on Ritalin HCl (Methylphenidylacetate) Injectable, Multiple Dose Vial. <i>Kurt Witton</i>	156	CORRESPONDENCE : Psychiatrogenic Illness	165
Preliminary Results with Fluphenazine (Prolixin) in Chronic Psychotic Patients. <i>John P. Holt, and Eleanore Wright</i>	157	Ordinal Position in the Family	165
		Criteria for Research	166

William Malamud

PRESIDENTIAL ADDRESS

PSYCHIATRIC RESEARCH: SETTING AND MOTIVATION¹

WILLIAM MALAMUD, M.D.

Just a little over a year ago my distinguished predecessor handed over to me the gavel of the President of the American Psychiatric Association symbolic of the high honor of this office, and the important responsibilities that are implied by it. I must confess that at that time, having come up through the ranks, so to speak, and having had the opportunity to appreciate the full implications of the functions of the President, the feeling that was uppermost within me was that of a realization of the responsibilities of this office and a profound hope that I would be able to prove worthy of the confidence that you have placed in me.

Today I come before you almost at the completion of this mission and, in reporting on the developments during the year, I have the satisfaction of knowing that, to the best of my ability, I have endeavored to further the highest interests of the Association and that this year's experience has been the most instructive, as well as the most stimulating, in my whole professional career.

I am deeply grateful to you for having bestowed this honor on me, for the confidence you have placed in my ability to carry these responsibilities and for the opportunity that you have given me to participate actively in the functions of this Association, of which I have now been a member for over 30 years. Added to this is a deep appreciation of the fact that both through election and appointment, you have provided me and this Association with a team of workers, including the officers, Executive Committee, representatives of the Assembly, members of staff and Committees, who have worked most enthusiastically and efficiently to assure the progress that has been achieved during the year. •

An important feature of this meeting is the opportunity it offers to all of us to take stock of what has happened during this period, to appreciate the progress that has been made by the Association and the profession of psychiatry, and on that basis to project plans for the future. I thought, therefore, that it would be most appropriate to undertake at this, the opening session, an analysis of events that have taken place, and to appraise their significance.

Our Association has grown rapidly, both in size of the membership and the complexity and breadth of its activities, and it seemed to me that it would be neither feasible nor necessary to attempt to cover all of these activities in the present statement. Instead of this, I would like to concentrate on what I consider to be the most important events that have taken place—events that are indicative of progress in the course of the general process of growth. Some of these have developed gradually, but have come to a climax at this time. Others have been initiated during this year through your efforts and those of the officers that you have elected. I feel that in lifting these items out for emphasis, their importance can be more effectively brought to your attention so that they may receive the consideration they deserve. The order in which they are presented does not imply degrees of greater or lesser importance. All of them represent milestones in the history of the Association.

1. *Definition of the functions of the Medical Director.* The establishment of the position of the Medical Director in 1948 and with it the organization of the Central Office and the purchase of the home of the Association were the results of an appreciation of the gradually growing complexity of our profession and the need for a central focus which would serve to coordinate the great variety of existing activities

¹ Presidential Address delivered at the 116th Annual Meeting, American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

and the launching of new ones called for both by our needs and our potentialities. The prospects of the great contributions inherent in this new phase in the development of the Association generated much enthusiasm, which was further nurtured by the broad vision, lofty imagination and unbounded energy so typical of Dan Blain and the leadership he provided both for the Association and his staff.

At the same time, however, the definition of the scope and content of this position has grown as a sort of patchwork, rich in ideas, but continually presenting need for clarification, and neither the membership nor the office staff were quite certain as to what it included. Questions began to come up as to lines of communication and authority, responsibilities and prerogatives, relations with the officers, Council, Assembly of District Branches, staff personnel, Committees and allied professional associations. This naturally resulted in some confusion, criticism and uncertainty, and when the present Medical Director came in, it became evident that a systematic definition of the functions of this office, with all that it implied, was essential both for him and the Association.

During this year we have become acutely aware of such a need and your officers, Executive Committee and Council, with the cooperative assistance of the Medical Director and his staff, have formulated a definition of this position and this will be presented to you in the Secretary's report. It is highly important that you give it your serious consideration, making use of it as a basis for operation at this time, but permitting flexibility of interpretation and possible change as time and circumstances dictate. The great importance of a clear definition of this office is obvious, particularly in view of the fact that it has come to represent the main focus of a continuum in an organization which by its nature is subject to constant change.

2. *The Reorganization of the Central Inspection Board.* As I view the developments in this Association during the period of my membership, I cannot think of any single development that has taken place in the past that surpasses, and very few that equal the important contribution that has

been made by the Central Inspection Board in improving the care and management of the mentally ill. This applies particularly to conditions in the public hospitals and the establishment of appropriate standards as guides for our own practice and for presentation to other medical groups and to the public in general.

Although all of us through the years have contributed to the process of its development, I think it can be said without any reservation that its establishment as a successful agency and its subsequent achievements were made possible primarily by the great devotion, leadership and persistent efforts that Dr. Tarumianz has invested in it, and the support he received from the members of his Board. Frequently, in the face of what appeared to be almost unsurmountable obstacles and resistance, he forged ahead most courageously with the result that now the first objective of this project has been reached. The establishment of desirable standards and the manner in which clinical facilities can be adequately inspected and their standards raised, albeit within realistic considerations, has been successfully demonstrated not only to our membership, but to the medical profession and the public. The Council has taken into consideration the fact that provisions have been made for including psychiatric representation on the Joint Accreditation Board, and has formulated a plan for reorganization of the Central Inspection Board, which is in keeping with new developments and which will be presented to you as part of the report of Council actions. On another and more festive occasion during this meeting, the Association will present to Dr. Tarumianz in a more eloquent way the recognition of the debt of gratitude we owe him. At this time, however, I do want personally to express our feeling of gratitude to him and his Board for a great contribution and our hope that we will continue to have the benefit of his wisdom and experience in the implementation of the new plan.

3. *Graduate Education in Psychiatry.* Over the past few decades most significant progress has been made in the better understanding of mental illness on the basis of the introduction of new methods of diag-

nosis, treatment, prevention and rehabilitation. All of these have led to a much more adequate, but also vastly more complex structure of dealing with these problems and, therefore, have made more obvious the rapidly increasing gap between knowledge acquired and the availability of manpower to implement the application of this knowledge to the problems of the mentally ill. With this came the recognition of the great need for an increase in the ranks of qualified workers. A great deal has been done in this direction, both within the Association and in interpreting our needs to the public in general.

The passage and implementation of the Mental Health Act and the great contribution that was made by the National Institute of Mental Health in this direction, the Ithaca conferences (1, 2) and a number of similar events, indicate the progress that has been made. In spite of these, however, and in spite of the rapid rate of increase in qualified personnel, there is still a wide gap between tools that have been developed and the availability of personnel to apply them. This involves not only the actual number of well-trained and qualified psychiatrists and workers in allied disciplines, but, what is at least of equal importance, the question of their distribution, particularly as it affects the staffing of public hospitals.

A number of us in this Association have taken cognizance of this situation and upon recommendation of the Long Term Policy Commission, which was formulated at the divisional meeting in Detroit, steps have been taken to develop plans for coming to grips with it. As a result of that, the Council has directed your officers to proceed, under the direction of my able successor and good friend, Dr. Robert Felix, to set up plans for a series of conferences, the purpose of which will be a frank appraisal of the factors responsible for these conditions and the formulation of recommendations of how to deal with them. Dr. Felix has entrusted the planning and steering of such plans to a committee that he selected under the co-chairmanship of Dr. Walter Barton and myself, and which will hold its first session at this meeting. It is obvious that the factors that influence both the general sup-

ply and the specific distribution of personnel are many and varied. Because of this it will be important to secure adequate representation of the variety of interests, experience and specific needs in the composition of participants in these conferences: directors of training centers as well as hospital superintendents; teachers as well as administrators. Furthermore, in the attempt to provide for more equitable distribution it will be necessary to emphasize not only the greater needs that exist in certain areas, such as for instance, the public hospitals, but also the great potentialities that are to be found in these areas, particularly in view of developments during the last few years.

4. *Development of Closer Relations between the American Psychiatric Association and Other Groups.* The rapid growth and increasing scope of our profession has brought to our attention the great need for adequate recognition by, and closer affiliation with, other professional and citizen organizations, particularly the general medical profession. The establishment within the structure of the American Medical Association of the Mental Health Council under the chairmanship of Dr. Leo Bartheimer and the development of similar committees in state medical societies, clearly indicate the progress that has been made towards the achievement of this goal. They have brought us into closer association with general medicine and its various specialties. A most encouraging manifestation of this trend was provided by the Hershey Conference last fall held under the sponsorship of the Committee on Scientific Activities of the American Medical Association. A major portion of this Conference was devoted to a discussion of the relationship between medical specialties and the American Medical Association. Both our Association and the Mental Health Council were represented and participated actively. The need for more adequate knowledge of psychiatric methods and principles in the general practice of medicine seemed to meet with wide agreement and this was also true in regard to the application of medical principles in the practice of psychiatry. It was also heartening to observe the genuine interest in the effort to understand the factors that have contributed to

isolation and to the need for the development of means to overcome them.

5. Closely related to this is the progress that has been made in regard to our relationship with psychology. I think it is safe to say that the difficulties that have been encountered in this area, particularly recently, were in a large measure due to a lack of adequate understanding and a consequent failure in communication. With the growing appreciation of this fact, earnest attempts have been made on both sides to remedy the situation and during this year we were particularly fortunate to have the wise counsel and energetic leadership of Dr. Felix in dealing with the problem. Both by training and scope of interest, he is especially well qualified to deal with it and throughout the year he has worked in close cooperation with the Committee on Relations with Psychology and succeeded in providing a good foundation for a solution. More recently the American Medical Association has invited us to a series of conferences to discuss our relationship with psychology as part of the general topic of the relationship between medical and paramedical professions. Dr. Felix, aided by Dr. Handler, Chairman of the Committee on Relations with Psychology, has participated in two such conferences and has represented us in a most statesmanlike manner. He has worked hard and wisely in promoting the best interests of the Association and we are looking forward to further progress under his guidance next year.

6. *Contributions of the Commission on Principles and Position on Current Issues in Psychiatry.* The rapidly increasing scope and wide ramifications of the activities of the psychiatric profession have led to the need for a broad but definitive statement on fundamental principles and on our position in regard to current issues in matters relevant to psychiatry, a statement which could be used in presentation to the public of the policy of our Association. In the past whenever the need for a statement of this type occurred it was presented by psychiatrists invited as individuals. It is true that in most cases the men called upon to present such statements, did so in a highly satisfactory manner, but whether or not it was in keeping with the general

opinion of the membership, it still remained essentially the statement of an individual. The Commission that was appointed for this purpose some time ago, has, under the chairmanship of Dr. Braceland and in consultation with the officers and Council, formulated a most appropriate statement of our policy. Since then Drs. Braceland and Ewalt have represented us on a number of occasions and each time they have successfully demonstrated the effectiveness of establishing a definitive policy and having it presented by experts who speak officially for the Association. It is especially important to keep this in mind when we are called upon to express our views on the need, for, and potentialities of such organizations as the National Institute of Mental Health and similar state and local institutions.

7. *Psychiatric Education in Medical Schools.* The fact that psychiatry has proven its status as an integral part of medicine and that, therefore, it must be given an adequate position in the medical curriculum seems to be so generally accepted that there should be no question as to the role it should play in teaching medical students. Nevertheless, the emphasis placed on the teaching of psychiatry as expressed, for instance, in the amount of curricular time allocated, still shows wide variations between individual schools, and this is also reflected in the degree of emphasis on psychiatry in the various medical board examinations. The National Board of Medical Examiners, which has quite justifiably come to represent the accepted standards for medical education, was one of the first to take cognizance of the importance of adequate psychiatric knowledge in the practice of medicine, and has begun to make provisions for the inclusion of psychiatry in the setting up of the examinations. Until now, however, this was limited to a few questions inserted in the Part Two examinations in medicine, pediatrics and public health. These were prepared by psychiatrists appointed by the Board and both Dr. Romano and Dr. Gaskill, who have served in this capacity, have represented psychiatry so effectively that during this year the Board has invited a group of psychiatrists under the chairmanship of Dr. Gaskill to

discuss the feasibility as well as desirability of setting up a separate examination in psychiatry, which is to be added to the examinations in the other five subjects in Part Two. The Committee has expressed itself in favor of this and the Board has approved this recommendation and has instructed our Committee to proceed with the setting up of such an examination for 1961.

This represents a very important development in the process of integrating psychiatry within medical education, with a beneficial impact on both. It will serve as a further emphasis of the need of sound psychiatric knowledge in the everyday practice of the physician no matter what branch of medicine he is in. At the same time it will help to accentuate the importance of teaching psychiatry to medical students, not as an isolated specialty, but as an essential part of a medical education.

8. Finally, I wish to call your attention to the important developments that have taken place in the area of *Psychiatric Research*, and to point out the fact that, although the progress that has been made in this area in recent years has been most impressive, we have just barely scratched the surface, and it is here that the Association is faced with both the greatest needs and the most promising potentialities. At the same time, I think that we are justified in saying that research is a basic prerequisite for any plans for the future if we are to attain the objectives spelled out in our Constitution. For the development of adequate methods of evaluation and treatment of mental illness depends upon scientific studies of the nature of disease and the manner in which it interferes with adjustment. Similarly, the organization of systematic programs of prevention depend upon the discovery, through research, of the causes of these diseases. This applies also to programs of rehabilitation, for it is essential to understand the nature of the residual defects if we are to institute measures which will adequately compensate for them.

Furthermore, if we are to establish appropriate standards for the care and management of the sick, these will have to be developed on the basis of adequately de-

signed and controlled studies of their validity. Finally, if we are to undertake the education of those who are to carry out these procedures or of the public in general, we will have to test through research the validity of the precepts that we plan to impart to others. All this must be kept in mind as we attempt to take stock of what progress has been made and what we can do to help in furthering it.

I do not purpose to undertake here a review of the present status of research in this field, or to attempt to point out the important advances that have been achieved during the current year. These I am sure will emerge in the course of the program of this meeting in which research reports play a very important role, just as they have in preceding programs. Suffice it to say that in my travels throughout the year both on behalf of the Association and as Director of Research of the National Association for Mental Health, I have found throughout the country a high degree of interest and activity in research in the whole spectrum of disciplines relevant to the study of human behavior and experience, both in health and in illness. Throughout all this one can discern the emergence of an encouraging sense of accomplishment and a recognition of what research has already contributed to a better understanding of mental illness and the manner in which this knowledge can be practically applied to dealing with the problems at hand. It is true that the degree of enthusiasm of individual workers varies from the one extreme of claims of exciting breakthrough, to the other extreme of skepticism and over-cautiousness. In most instances, however, the sense of accomplishment is adequately balanced by a healthy recognition of the magnitude of the task, with the resulting determination to tackle it courageously, but also realistically.

"What can the Association do to foster and promote this work? Some years ago, Drs. Whitehorn and Zilboorg, representing the Research Committee, of which Dr. Whitehorn was the Chairman, presented a review of the trends in American psychiatric research at that time(3), and I find that the basic principles expressed then could well serve as guide lines for our Association today. The question posited was "What can

the Association do in promoting activities of this type (research) that would be in keeping with the goals and the interests of the Association?" They went on to say that: "We do not believe that this Association would wish their Research Committee ever to attempt to control or direct various investigations; but we do believe that they would wish us to encourage research efforts and help in whatever way might be found profitable to facilitate the interchange of them among research workers." And it is with this in mind that they proceeded to set forth a series of recommendations.

The Association certainly cannot undertake the control or direction of research investigations, nor can it be expected to act as a financing or sponsoring agency. This must be left to those who have the wherewithal to provide the funds and facilities that are essential. The Association can, however, play an important role by stimulating the interest of its members and others, particularly younger workers, and by bringing its influence and prestige to bear upon those who are in a position to support research, to provide the adequate facilities in which effective work can be carried out. Such encouragement and facilitation can be achieved through two principal functions: The assurance of adequate settings and the fostering of appropriate motivation.

Insofar as the setting is concerned, many of the recommendations proposed in that earlier statement have actually been implemented. Federal and state agencies, private foundations and citizens organizations have provided increasing funds to finance the rapidly growing number of projects in this field. These have provided for the support of personnel, for materials and apparatus and even for construction of research buildings. The Association has played an important role in making this progress possible through the activities of a number of its Committees, but a great deal more remains to be done. In the first place there is now, and there will be in the future, a continually increasing need for funds. In spite of the generous financial contributions that have been made, particularly during the last few years, and actually because of the successful achieve-

ments that were made possible by these funds, the scope of the problem has become much greater. New knowledge has brought up more questions, and new methods devised have provided us with more adequate tools in search for answers.

Secondly, there is need for reorientation in regard to the distribution of the funds that are made available. With the increasing complexity of research methodology and scope it has become obvious that our greatest need is for adequate manpower, which means a considerably stepped up recruiting and training program. This means also that some portion of the funds hitherto used for direct research projects, would have to be used for training of scientists. Another shift in distribution should be considered in regard to the type of institution, including the background of its staff and the facilities available, that can be considered most likely to make valuable scientific contributions. It is quite natural, and perhaps justifiable, to determine this on the basis of past performance. But frequently an institution or an individual worker with the history of a signal contribution in the past, will receive priority consideration even if the grant is for work in an area quite different from the one in which competence has been demonstrated. This is especially likely to occur if the choice lies between well-known, experienced scientists and younger ones who have not yet established their reputation, or between institutions with "basic research" traditions, as compared with more recently initiated programs that are more likely to be clinically oriented. In many cases this is justified and certainly reduces the hazards of a gamble. Just as frequently, however, one fails to consider that success in one branch of research does not necessarily imply efficiency and understanding of all of them; that ready availability of pertinent material (particularly clinical) adequately evaluated is as important as the quality of scientific methods, and that in medicine clinical insight and experience are basic in the study of disease processes.

One must also keep in mind the current tendency to set up priorities and concentrate all efforts on some special subject at the expense of all others. This may be deter-

mined by the emergence of some problem which is of particularly pressing concern to society, or it may be conditioned by the claim of a "breakthrough" actual or spurious, such as reported discoveries of "ultimate causes" or "universal cures." In either case, the general effects can be equally disturbing. It leads to a frantic scurrying to get on the band wagon, particularly in situations where one must take into account the vacillations of public opinion.

Less frequent but likely to be just as unfortunate is the tendency of the skeptics to react to all new ideas or findings hypercritically and in their concentration on "objective criticism" impede the development of new ideas, even if they are promising, and discourage investigations based upon them. Research, if it is to lead to progress, must take into consideration the need for a certain degree of flexibility which would assure freedom of choice not only in regard to the particular aspect of the problem which is in keeping with the specific interests and skills of the individual worker, but also the design and methodology which he considers to be the most adequate and applicable to the particular questions he posits. It is true that the design and methodology used in testing the hypotheses as well as the manner in which data are recorded and analyzed and conclusions are arrived at, must follow certain fundamental criteria of reliability, which will assure the maintenance of a critical attitude and avoidance of wishful thinking in the interpretation of the data. It is equally important, however, to remember that the specific nature of design and methodology may differ in their applicability to the variety of disciplines involved. In the first place different sciences (such as, for instance, the social as compared with the physical) have developed at different rates of progress, so that some of them, at least as regards their objectivity and reliability in scientific research, are not quite as far ahead in the perfection of techniques and criteria as some others are. This may be due to the fact that some sciences of human behavior because of their relatively greater complexity have not had as much of an opportunity to develop as rapidly as others and, therefore, lend themselves less

easily to exact standards of measurement. In such areas it is well to accept reality considerations, and, while always striving for improvement in the quality of design and technique, we have to make use of crude instruments, where more refined ones are not as yet available.

Secondly, it is important to keep in mind that the different sciences of human behavior may be functioning in different universes of discourse and may not be subject to uniform criteria of standardization and measurement. This means that no matter how nearly perfect a given technique may be in one science, it may not ever become applicable to the study of phenomena in another one. Some of the methods, for instance, used in the study of emotions or feelings may never lend themselves to the standards of measurement that are useful and utilizable in biochemistry.

The importance of maintaining an attitude of flexibility in the process of evaluating the adequacy of a proposed scientific study, applies to all phases of research, but is particularly indicated in the behavioral sciences, because of the greater spread of applicable techniques. And yet during the last few years we have witnessed a growing trend of over-emphasizing the value of "exact" methodology and uniformity of standards. This trend, which could be characterized as a "cult of objectivity," has already had an important influence on psychiatric research. It is true that in its emphasis on critical judgment and valid criteria, it has helped to curb unrestrained flight of imagination and sloppy methodology. But the over-glorification of objectivity and the insistence on rigidly single standards of acceptable methods has resulted in a concentration on certain phases of the science of human behavior at the expense of other very important ones.

These are but a few of the factors that are operative in the setting of research and can have an important impact upon both the scope and ultimate value of this fundamental phase of our activities. Our Association should be constantly alert to these developments and their implications, and while not attempting to control or direct research, it should, as a professional organization have a well defined policy in

regard to the fundamental issues and, through its appropriate Committees and Commissions, be prepared to present it as a guide for action where it is indicated.

So far my discussion of what the Association can do to promote research dealt with the character of the setting and the role it plays in determining the degree of effectiveness of this work. We have assumed that there always have been and that there always will be certain persons who devote some or all of their interests and time to research. If, however, we are interested not only in facilitating the activities of those who are already engaged in this work, but also in stimulating an ever increasing number of persons who will be likely to develop and maintain an interest in it to begin with, we will have to consider the question of whether such persons, either through nature or nurture are impelled to do so by some basic need or urge for probing the unknown. In other words, can we speak of *motivation* as an essential or even primary determinant in the choice of research as a life work? If this is so, then the setting is of importance primarily in a measure as it either facilitates or impedes the effective fulfillment of such an urge. Furthermore, if motivation is accepted as an important and fundamental factor in determining a primary interest in research, the Association should strive to stimulate and foster it amongst its members and others who could be attracted to it.

In medical (including psychiatric) research, particularly that aspect of it which is referred to as clinical investigation, we have ample demonstration of a positive answer to this question. In most instances the clinical investigator is motivated by very definite needs, usually consciously appreciated. It is true that these needs may be based on a variety of practical considerations, such as the wish for recognition and status, the pressure in regard to promotion or retaining of a status quo in a department and others of a similar nature. More frequently, however, than some skeptics will admit, the motivation stems to a greater or lesser extent from the same source as does the practice of medicine in general, namely, the urge to be more effective in the treatment of illness. This is

particularly true in the admittedly rare instances of fundamental contributions. Semmelweis, Freud, Pasteur or Fleming, confronted by certain life destroying processes in nature, and finding themselves unable to counteract them by existing methods, have taken up the challenge of nature and have turned some of nature's own weapons against the disease producing causes. In other words, research of this type represents a purposeful activity whereby man, finding himself at the mercy of a variety of random processes in nature that tend to produce disease, undertakes a systematic and orderly search for methods which will control or eradicate the life destroying processes.

In discussing the question of motivation, however, we have to reach out beyond the bounds of what is described as clinical investigation. The great progress that has been achieved in psychiatric research in the last few years has in a large measure been due to an extension of its scope to all of the basic sciences relevant to human behavior, more particularly those of physiology and biochemistry and this has resulted in a crossing of boundaries. Thus many studies that have started out on an empirical level of the immediate practical applicability of new methods of treatment (such as shock treatment and pharmacotherapy) have brought up the need of ascertaining their fundamental mechanisms through research in physiology and biochemistry. Similarly, an impressively large number of workers in the basic sciences have, in the course of their studies, come to recognize the applicability of their findings to the understanding and treatment of disease and have extended their work in that direction. Actually we find that the core of psychiatric research at the present time is to a large extent made up of a combination of both clinical and basic investigations without any clear cut line² of demarcation between the two. This means, therefore, that in posing this question and its implications in regard to the clarification of our objectives, we cannot limit ourselves to any one phase of this work, but must also ask whether the concept of motivation, which was postulated as operative in clinical investigations, is also applicable to

the whole scope of psychiatric research and, indeed, to science in general.

The question is, of course, highly controversial and admits of no universally acceptable answer at this time. The prevailing view of men of science has been that "basic" science deals with matters of fact and has no place for values. It describes facts and their interrelationships, which may lead to conclusions, but admits of no goal-directed motivation and involves no moral imperatives. This view has been challenged on a number of occasions and has been presented particularly convincingly in a recent statement by R. B. Lindsay, professor of Physics in Brown University, under the title of "Entropy Consumption and Values in Physical Science" (4).² He takes his point of departure from the statement that science is a method for describing, creating and understanding of experience. Whereas description may be regarded as passive and essentially impersonal, creation (devising of experiments) and understanding (building of theories) are active and personal, and imply individual motivation on the basis of an intrinsic urge. In terms of experience this urge is akin to Kant's Categorical Imperative and its nature is suggested by the principles of Thermodynamics. Professor Lindsay, therefore, suggests that one may call it the *Thermodynamic Imperative* and that it may be regarded as urging "all men to fight always as vigorously as possible to increase the degree of order in their environment so as to combat the natural tendency for order in the universe to be transformed into disorder, the so-called second law of thermodynamics."

As stated above this concept is derived from a consideration of the theory of Thermodynamics, and the basic principles with which it operates, namely, its first and second laws. The first law is that of the conservation of energy, or the fact that through all its possible transformations the energy of the world remains constant. The second law is that of *Entropy*, according to which there is always a loss of available energy in the course of energy transforma-

tion, and a constant trend in all systems to move from a state of order to one of disorder. Generally speaking as applied to nature as a whole, this law appears to be inexorable, inevitably leading to a state of complete randomness and lack of available energy, eventually to reach a dead level of temperature.

In some specific instances, however, the trend may be reversed, leading to a decrease or consumption of entropy and the emergence of order out of disorder. The most striking is that manifested by the living organism, where we find that from a random collection of atoms there is the synthesis of cells which in turn arrange themselves in the most intricate orderly system of an organism. Life and reproduction, therefore, can be regarded as an example of entropy consumption. Another example is that observed in the function of the human nervous system as manifested in the processes of thinking and communication, both of which are characterized by a progression from randomness to order, and which show their highest expression in scientific research. No one will deny that in this process the scientist is impelled by the urge to acquire more knowledge, more understanding and greater orderliness, but this also coincides with a decrease in entropy. In the case of life and reproduction this urge is an instinctual one. In the case of research it is a consciously appreciated need to extend the light of knowledge and orderly understanding into the mysteries of the unknown, and in this way to take up the challenge of nature and thereby check, even if only temporarily and locally, the inexorable progress of entropy.

The concept presented by Professor Lindsay is both thought provoking and inspiring. We find its parallel in philosophy in Kant's Categorical Imperative, in Plato's idea of the continuous striving of man for the Agathon or the principle of the good and the just and in Spinoza's statement that "there is but one end for the sciences to which they all must be directed, namely, to attain the greatest possible human perfection." In medicine, more specifically psychiatry, we find this concept expressed in one of Freud's most profound contributions, *Beyond the Pleasure Principle*, in

² I wish to acknowledge gratefully the permission given by the Editor of the *American Scientist*, to use this material in the present publication.

which the idea of entropy consumption is represented by the antithesis of the Life (reproductive) and Death (ego) instincts(5).

The fundamental relationship between Lindsay's idea of a thermodynamic imperative and the nature of the motivation postulated as basic in clinical research is obvious, both of them finding their highest expression in Schweitzer's principle of "reverence for life." The fostering of this principle and the establishment of a setting in which it can be most effectively implemented is to be regarded as a fundamental objective of our Association.

DR. WILLIAM MALAMUD
Eighty-sixth President—1959-1960

A BIOGRAPHICAL SKETCH

BERNARD J. ALPERS, M.D.¹

By training and choice, it was inevitable that Dr. William Malamud should become concerned with the mind and its problems. With the wisdom of retrospect, it is possible to follow his development to its fruition in psychiatry, and to wonder how any other field of medicine could have attracted his particular talents. Even the influences of his early life, long before his college and graduate training, were directed toward his eventual fulfillment.

He was born on May 5, 1896, in Bes-sarabia, which had a mixed population and at different times in its history alternated between being a province of either Russia and Roumania. He came to Canada in 1911 at 15 years of age. His subsequent development and accomplishments are in the finest traditions of freedom. He had no knowledge of English when he came to Canada, and no public school instruction until he entered McGill University in 1916. Prior to this he received private instruction at home, and worked in a factory in order to help support his family. After several years of study and work he took the examinations for a brevet in the province of Quebec, passed these successfully, and was accepted for admission to McGill University in 1916, graduating from its school of medicine in 1921. His graduate training in psychiatry was spent in the Boston Psychopathic Hospital under the direction of C. Macfie Campbell. It is characteristic of his broad approach to the field of psychiatry, that he also spent a year in training in neurology in the Mt. Sinai Hospital in New York. Following this he spent two years in obtaining further grounding in psychiatry, neurology, and philosophy, dividing his time between Hamburg, Heidelberg, Vienna, Zurich, Paris and London.

After his return from abroad Dr. Malamud entered the Massachusetts state hospital system where he served in the

Foxboro State Hospital for three years (1926-1929). Here he not only added to his broad psychiatric experience, but he instituted also a program of research, and gathered around him a group of young and enthusiastic psychiatrists. It became quickly apparent, due to his stimulating influence, that a state mental hospital was a rich source of material for study and research, and that all it required was a group of dedicated men trained in the academic tradition. He left Foxboro in 1929 to become Associate Professor and later Professor of Psychiatry in the University of Iowa (1929-1939), leaving this post to become Clinical Director and Director of Research in Worcester State Hospital (1939-1946). While there he was made Professor of Psychiatry in Tufts College School of Medicine. The Worcester State Hospital is rich in tradition and has graduated many leaders of psychiatry in the United States. Dr. Malamud not only fulfilled this old, but added his own tradition, for it was here that he carried out some of his most interesting researches into the elusive problem of schizophrenia. As was to be expected from his training and background, his approach to this, as to all problems in psychiatry, was eclectic, and his efforts were directed toward elucidation of both mental and physical influences in the disease. He was particularly concerned with the endocrine influences in schizophrenia.

In 1946 he became Professor and Chairman of the Department of Psychiatry in Boston University School of Medicine, and Chief of the Psychiatric Service, and later Psychiatrist-in-Chief of the Massachusetts Memorial Hospital. In 1958, he left this post to become Research Director of the National Association for Mental Health, a post which he holds at the present time.

INFLUENCES IN DEVELOPMENT

This, in brief, represents the barest of outlines of the professional development of

¹ 11 49th St., Philadelphia 39, Pa.

a psychiatrist who from the beginning of his career was recognized by his colleagues and teachers as one who was destined to scale the heights, and who has now been honored, after a long career in teaching and research, with the Presidency of the American Psychiatric Association. His influence as a teacher has been felt not merely as an expositor, a role in which he excels, but to a much greater degree in his eclectic approach to a field which is rent asunder by many divergent and often conflicting viewpoints, not only as regards psychodynamics, but in the more practical field of treatment. He represents a rare combination of broad academic perspective, skill in teaching, and the ability to apply in treatment what it is so easy to teach. The many years spent in the study of hospitalized and non-hospitalized patients have provided him with knowledge of mechanisms and of their application in the treatment of the sick, and have matured a feeling for his fellowman which is apparent in all his human relationships. Psychiatry, more than any other field of medicine, is composed of many divergent groups. Perhaps this is inevitable in view of the elusiveness of problems relating to the mind and the emotions, and in particular of those of body and mind. There are many who choose the specific in their approach to psychiatric problems, but relatively few who attempt to envision the whole and to unite what appears to be divergent. Dr. Malamud's great contribution as a teacher is to be found in his eclecticism; his effort to find what is good in the many theories of mind, body and emotion, and to unite where this is possible without damage to facts and practical experience. This approach has come about by means of significant influences in his life and career.

He was raised in a polyglot background which early in his life made him recognize varieties of viewpoints and their nuances. The language in his home was Yiddish, but he spoke and read Russian and Roumanian, since the majority of the population of the province of Bessarabia was a mixture of the two nationalities. He read Hebrew and Aramaic as a student of the Holy Scriptures and the Talmud, under the influence of his uncle who was a Rabbi, and who was responsible for his introduction to Hebrew

and the Talmud. Later he learned English as a young immigrant of 15 years, and to this he added the knowledge of French, acquired while living in the province of Quebec. In his travels abroad he added to his speaking and reading knowledge of German, which was so sound that he was able to read fluently the difficult German of philosophical writings. Languages were easy for him, but though he had a reading ability in all the languages which he learned, more important still was a background in their tradition and history. Those who have had any contact with him can testify readily to the ease with which he acquired and used the many languages which he learned. They have served a utilitarian purpose, but more important than this, they have given him a feeling for the people who use them and for their institutions and traditions. Only a man with Dr. Malamud's impetus for learning would have made use of acquired languages as a means to understanding.

Problems of philosophy and of abstract thought have fascinated him all his life, and it was not mere chance which took him to Karl Jaspers and Ernst Cassirer during his years of study abroad. But before this he was introduced to analytical thinking and to questions of exegesis and relevance in his study of the Talmud. It is difficult to indicate in brief the type of training which this implies. The Talmud is the repository of the great oral traditions of the Hebrew Scriptures, composed of many books and characterized by Rabbinical interpretations of vexatious scriptural passages. The student of the Talmud, young or old, is confronted often with conflicting rabbinical interpretations, and is taught to analyze and to interpret. The result was a training in abstract thinking, in the importance of distinctions and relevance, and in the Scriptures in general. All this was part of Dr. Malamud's background, and it influenced him greatly in his early life, both in regard to content and in the use of his mind. It requires relatively little imagination to predict that a background in the Talmud and its problems and training could lead eventually into the broad field of psychiatry.

His knowledge of Hebrew led to his introduction to the works of the great He-

brew poet Hayyim Nahman Bialik, who was himself a Talmudist and a fine Hebrew scholar. Bialik, who later emigrated to Palestine, was instrumental in the revival of Hebrew as a language, but was critical of some of the rigidity of his Talmudic training. His poetry and the broad scope of his philosophy fascinated Dr. Malamud, but he was also instrumental in creating dissatisfaction with his Talmudic background. It failed to resolve some of his problems, and led to doubt. It was at this point that he discovered Spinoza, who has remained for him the ideal philosopher, just as Bach and Beethoven represent for him the summit in music. He first met Spinoza in a life of him which had been translated into Hebrew, and he was impressed by Spinoza's blameless life, his doubting of orthodoxy and revelation, and by the fact that Spinoza's rejection did not arise out of ignorance, for he was a fine Hebrew scholar and a learned Talmudist. In seeking for a philosophy of life which could reconcile the emergence of religious doubt, Dr. Malamud discovered the pantheism of Spinoza, and adopted his philosophy. His interest in Spinoza led to a break with some of the concepts of his uncle who had taught him Hebrew and Talmud. Spinoza had been excommunicated by his congregation in Amsterdam, and to accept him in any way was unacceptable to an orthodox Jew.

His interest in Bialik's poetry and his discovery of Spinoza, led to the decision that his interest lay in philosophy. While still in Europe he read the ethics of Spinoza carefully, and he regards them today as the finest expression of human strivings. He has continued to study Spinoza, whose theory of the emotions, that body and mind are one, is modern in every respect. It was at this point also that he decided to become a doctor and to concern himself with problems of the mind. He has not failed in this resolution.

In addition to Bialik and Spinoza, Dr. Malamud sought further indoctrination into philosophy when in Heidelberg many years later he spent considerable time with Jaspers and Cassirer, the latter launching him on the road to philosophy in organized fashion. He has been greatly influenced also in his interest in the human mind in the

writings of Dostoevsky and Romain Rolland.

Of his other teachers, among those who have influenced him most has been Bleuler, whose profound and global analytical approach impressed him greatly. He was analyzed by Paul Schilder whose brilliance and versatility he admired, in particular his competence in both neurology and psychiatry. Finally, his days in the Boston Psychopathic Hospital brought him under the influence of C. Macfie Campbell, Professor of Psychiatry in Harvard Medical School. Like all those who had the opportunity to study under him, he admired Dr. Campbell's survey of the total personality, his insistence upon a global survey of the patient's problem, and his skill as a clinician and teacher.

What makes a great psychiatrist is as difficult to define as what makes a great doctor, but given a conspicuous example it is possible to indicate, with broad strokes, what circumstances have conspired to bring this about in the case of William Malamud. For what has emerged in full flower has been a rare combination of the best features of academic knowledge and an exceptional ability to apply these to the vital problems of human beings, catalyzed by warmth and understanding. His early background provided him with the impetus to explore problems of the mind and of abstract philosophy. Whether this constitutes the preferred approach to the field of psychiatry for all is debatable, but for Dr. Malamud it tended to sharpen his mind, and to interest him in a field of medicine which he chose as his own even before his formal medical training began. His approach to psychiatry has remained humanistic, not only in the many disciplines which he has combined in the development of his holistic concept, but in his handling of patient problems. Though he has taken an active part in laboratory research in emotional and mental disorders, his main investigations have been in the broad field of psychopathology as they involve psychological, social and biological factors in human behavior. But psychiatry is, after all, a clinical discipline and its goal is the relief of illness of the human mind and emotions. An understanding of the mechanisms of obsessions and phobias

is of little consequence unless it can be applied to those who suffer with them. In this Dr. Malamud excels, and both his students and colleagues give ready testimony to his skill as a superb clinician.

It may well be that the psychiatrist of the future will be versed in chemistry and physiology, but fundamentally his problem remains that of understanding of human behavior. Regardless of the trends of future

investigations, it will always be presumed that the psychiatrist will reflect as deep an understanding of human needs and motivations as it is possible for humans to acquire. If he can develop his understanding with the broadness and diversification of William Malamud, he will have provided psychiatry with the best possible base for the understanding and care of patients with emotional and mental problems.

CHILD PSYCHIATRY : RETROSPECT AND PROSPECT

LEO KANNER, M.D.¹

On May 19, 1933, at a meeting of the Swiss Psychiatric Association in Basel, Dr. Tramer presented a paper in which he advocated the recognition of a medical specialty devoted to the study, diagnosis, treatment, prognosis, and prevention of the psychiatric problems encountered in children. He discussed briefly the advances made in the investigation of central nervous system morphology, the Freudian and Adlerian emphasis on the significance of infantile experiences, the insights gained from the relatively recent discoveries in endocrinology, the advent of experimental and developmental psychology, and the work emanating from the Pavlovian laboratories. He concluded that a body of knowledge had been assembled which warranted the acknowledgment of a separate scientific concern. He pointed to the necessity of abandoning the traditional position of the profession; academic departments of psychiatry had acted as though children were essentially miniature adults and, therefore, regarded training in adult psychiatry as a sufficient preparation for work with children—if, indeed, such work was included in the scope of professorial curiosity.

The day on which Tramer delivered his address may be registered as the birthday of the term *Child Psychiatry*, introduced by him in its German equivalent as an overall name for the theoretical, investigative, and clinical occupation with deviations from the usual behavior in early life. Tramer imparted to the term the benefit of literary respectability in the title of a journal which, founded in 1934, has just passed the quarter-century mark a few months ago. Also in 1934, an international congress in Paris, the first of its kind, voted, after some initial opposition, for the official acceptance of the term *psychiatrie infantile* as a fitting designation for the new discipline. In 1935, the publication of my textbook, *Child Psychiatry*, helped to win popularity for the name in the English-speaking

regions as a comprehensive, universally employed heading for a large and ramified area of medical activity, taught in universities, practiced in hospitals, clinics, and private offices, contributing to present-day research in the behavioral sciences, and sharing its findings and their practical applications with all agencies dedicated to the welfare of children.

Of course, the same principle still holds as that which is evident in the Biblical account of Genesis: The name of a thing is preceded by its creation. The reality and the concept of child psychiatry were there in the beginning of the 1930's and the appellation suggested for it by Tramer was merely the verbal label for a recognized existence. It took more than a century for this existence to come into full being but, then, what are a dozen or so decades if weighed against the history of human endeavor?

Child psychiatry did not, indeed, arrive on the scene as the unified structure as which it has evolved in our generation. Collections of different shapes and sizes of building stones, for a long time not even conceived as such, were piled up at some distance from each other, then brought haphazardly into casual relationship, and eventually carried together to become parts of an integral edifice. A historian wishing to gain an adequate perspective of these developments can hardly do so without a review of the originally disparate sections and the manner of their convergence.

It is safe to say that any kind of practical effort to do something for behaviorally defiant children began at the start of the 19th century with a desire to find a way to help mental defectives.

The era of emancipation from political and theologic absolutism, the new gospel of the rights of man, the impact of the encyclopedists, and the French and American revolutions had in their wake a spurt of humanitarian reform activities. The ideas about the treatment of the insane, the slaves, the prisoners, the blind and the deaf came in for extensive revision, and each

¹ Professor Emeritus of Child Psychiatry, The Johns Hopkins University; Visiting Professor of Psychiatry, University of Minnesota.

group had its vigorous spokesmen. The feeble-minded were not left out. Jean Itard's untiring attempts over a period of 5 years did not accomplish his avowed purpose of transforming the wild boy of Aveyron "from savagery to civilization" but introduced the then novel thought that a combination of physical and educational measures might raise the performance level of intellectually retarded children. Itard's work was taken up by Edouard Séguin who, leaving France as a political émigré, imported the concept and methods to our shores.

It now sounds unbelievable that in the early years of the 19th century there was still nowhere in the world a residential arrangement for the teaching and the medical care of mentally defective children. It was not until 1841 that the quixotic attempts to cure and prevent endemic cretinism led young Dr. Johann Jakob Guggenbühl to open the first such institution on the Abendberg near Basel in Switzerland. His missionary zeal proved so infectious that kings, scientists, philanthropists, and famous writers undertook pilgrimages to the Abendberg, and soon many similar places were founded all over the European continent. One visitor from the United States, Samuel Gridley Howe, was so overwhelmed by what he saw that he suggested the name "Holy Mount" for the Abendberg. He persuaded the authorities of the Commonwealth of Massachusetts to allot \$2,500 annually for 3 years for an "experimental school," which started in October, 1848, with 12 retarded patients in a wing of the Perkins Institution for the Blind. This was the modest nucleus of what is now the large, modern, scientifically conducted Fernald State School at Waverly. New York followed in 1851, Pennsylvania in 1854, Ohio in 1857, Connecticut in 1858, Kentucky in 1860, and gradually all states but two have seen to it that residential facilities were made available for the care of the feeble-minded. Much valuable work has been done in the area of mental deficiency. The old notion of the unitary character of the condition was dispelled when, beginning with Langdon-Down's description of mongolism in 1866, an increasing number of specific syndromes were singled out. This process is still going on, and the time does

not seem too distant when an acceptable etiologic grouping can be envisioned on the basis of neurologic, metabolic, genetic and psychologic characteristics.

This earliest heap of building stones of child psychiatry set a pattern for those which followed, a pattern of self-containment. For a long time, the students of mental deficiency stood alone, both isolated and self-isolating, depending on their own resources. They published their own periodicals, formed their own associations, and held their own conventions. There was a paucity of interchange between them and the representatives of academic psychiatry.

As for the latter, behavior problems of children interested them only as they seemed to fit diagnoses in accordance with the classifications devised for adults. Everything else was kept out of the few monographs on "psychic disorders," "mental diseases" or "insanity" of children. Interest in therapy was restricted by fatalism which saw in the reported disorders the irreversible consequences of heredity, degeneracy, overwork, excessive masturbation, or religious preoccupation. Neither Kraepelin's monumental work nor Bleuler's classical textbook had anything to say about the psychopathology of childhood. The second edition of Ziehen's treatise on the mental diseases of childhood, published as late as in 1926, was a therapeutically sterile translation of adult psychiatry into terms of how much of it one might find in children.

It may be said without fear of contradiction that traditional psychiatry had offered next to nothing to the understanding of the behavior of the individual in the initial stages of his growth. It was around 1900 that the attention of the profession was directed toward early life experiences as possible sign-posts for later neurotic or psychotic maladjustment. Freud abroad and Meyer in this country introduced a dynamic attitude which saw the origins of present trouble in happenings in the past. Mental illness came to be evaluated as a climax of difficulties which had been evolving for a long time as a particular person's reactions to his particular life situation. Biographic exploration became an obligatory part of psychiatric history taking. Biography, if pursued consistently, leads always back to

the days when each patient was a child. Thus, around the turn of the century, psychiatric interest was for the first time directed toward childhood. But even this interest was still chiefly anamnestic, retrospective, historical. It pertained to the early years of persons who at the time of inquiry had already attained adulthood or at least adolescence. Childhood, therefore, was still dealt with as something like an anthology of reminiscences. There still was no immediate psychiatric contact with children. Even Freud, who so clearly understood the influence of early experiences, had his theory of infantile sexuality all worked out and published in 1905, three years before he ever saw any one child professionally, and then only indirectly via the physician father of the now almost legendary *Kleine Hans*. Then followed a decade in which a few psychoanalysts decreed speculative ex-cathedra interpretations on little strangers until Anna Freud, less addicted to ritualistic techniques, taught child analysis as a method of treating real children in real family settings and not merely as bundles of instincts offering themselves for would-be omniscient and tediously repetitious exegesis.

While psychiatrists of both analytic and non-analytic persuasion began to add a limited number of youngsters to their sphere of curiosity, another group, which was in everyday contact with numerous children, had for some time become dissatisfied with the status quo. The breezes of liberalism blowing through central and western Europe had wafted the ideas of Pestalozzi and Fellenberg into the minds of progressive school teachers. The Procrustean methods of cutting or stretching pupils to fit the exact contours of the curricular bed gave way to a search for means of helping individual students incapable of conforming because of physical, intellectual, or emotional shortcomings. In those days, no inspiration could be expected from psychiatrists who for the most part were immured with their patients in the sequestered isolation of mental hospitals or beyond reach in the cloistered aloofness of academic splendor. A group of educators in Austria, Germany, and Switzerland took the initiative and founded the movement of

Heilpädagogik, or remedial education. The contributions made by this group to the study and scholastic treatment of the learning and behavior problems of school children should not be underestimated. This, of course, was not child psychiatry as we know it today but cannot be disregarded as one of the building stones of the emerging specialty.

In fact, it was from the field of education that the impetus arose for the gathering of another important set of building stones. After compulsory school attendance had become an entrenched feature in most civilized countries, the public school authorities in Paris, bothered by considerable inequalities of classroom achievement, turned to Alfred Binet for an explanation of this phenomenon. Binet and his assistants, examining thousands of children of different ages, established a scale which was based on empirically ascertained norms of performance with regard to scholastic ability. With the help of this procedure, it was possible to learn to what extent any one pupil conformed to, or deviated from, the norm or average. The first draft of the scale was made public in 1905; a revision came out in 1908; a third, improved set was presented in 1911, the year in which Binet died. Binet's work set the pace for studies of the natural history of human development, no longer as a matter of abstract arm-chair wisdom meditating about the species as a seemingly homogeneous group but in terms of concrete observations and measurements of real individuals viewed as heterogeneous specimens. There came a multitude of diaries, questionnaires, trait inventories, and test batteries, culminating in the body of developmental psychology.

Children, at long last, had begun to be seen and heard. The rod and the dunce cap ceased being the only resort in attempts to cope with the behavioral nuisances of young nonconformists. The spirit of tolerance which had declared open war on all forms of despotic harshness, brought about a reexamination of the prevailing relationship between the arrived and the arriving generations. In far away South Australia, a number of civic-spirited men and women found the punitive attitude of the courts toward young offenders objectionable;

they succeeded in 1895 in the establishment of juvenile courts in which delinquent children were to be handled separately and differently from adult violators of the law, with an emphasis on rehabilitation instead of retaliation. In 1899, the states of Illinois and Colorado passed similar statutes. Within a decade, juvenile courts began to spring up in all civilized countries. Some of the judges were not satisfied with the job of meting out justice in the form of verdicts and sentences. They wanted to find out *why* the children brought before them had been driven to their transgressions.

It is, at this time, difficult to realize that this mode of inquiry represented a major innovation. Antisocial acts had been regarded by Prichard in 1835 as the results of an innate "morbid perversion of the feelings, affections, and active powers," by Kahlbaum in the 1870's as the manifestations of a "faulty development of the moral fiber systems," and by Lombroso even later as the outcropping of inborn propensities. A major change in the concept of human behavior had to, and did, occur before the times were ripe for the work of William Healy who, discarding the obsolete notions of delinquency as a chromosomally preordained destiny, devoted himself to the study of motivations in the light of the young offender's life situation. The title of his book, *The Individual Delinquent*, published in 1915, indicates a transition from abstract speculation about a nebulous something called delinquency to the concrete occupation with the personalities of specific youngsters and the motives underlying their socially unacceptable performances.

The introduction of the juvenile courts is but one link in a chain of events which had caused the Swedish sociologist Ellen Key to predict that the 20th Century would be known as the century of the child. The first decade witnessed the birth of developmental psychology and, in psychiatry, the shift of focus from the nosographic allocation of supposedly unheralded mental diseases to a search for psychodynamic principles that might explain personality disorders as consequences of unfavorable interplay between the patient and his environment. With this kind of orientation, it

became possible to think in terms of therapeutic intervention and prophylactic interception. The idea of prevention had taken root in 19th-century medicine and had settled in the public mind. The question was raised whether interferences with mental health might be made as accessible to preventive measures as certain inroads on physical well-being had proved to be. This hope found a vigorous advocate in Clifford Beers, whose enthusiasm and organizational talent led in 1909 to the creation of the National Committee for Mental Hygiene.

The mental hygiene movement had for its slogan the prevention of insanity and delinquency. For this, there could be no better starting point than the appearance of the earliest signs of misbehavior in the formative years of childhood. Hence, it became a part of psychiatric responsibility to anticipate and, if possible, preclude full-blown pathology instead of merely sitting back and waiting until it had assumed major proportions. This soon came to mean a preparedness to study and treat problems at their incipency, not so much for what they might lead to in the future but as issues of the present calling for the relief of emotional discomfort, regardless of its magnitude or possible prognostic implications. The psychiatric concept of childhood thus underwent a succession of changes within a short span. It was at first encompassed in the specialty as a retrospectively significant antecedent of adult maladjustment, *with an eye on the past*. It is then viewed, with a bit of Cassandra-like foreboding, as a potential precursor of adult malfunctioning, *with an eye on the future*. It was finally granted the right to exist on its own terms, neither as history nor as premonition, but as worthy of being seen in the perspective of immediacy, *with an eye on the present*. The time was ripe for the remedial consideration not only of glaring departures from normalcy but also of what Douglas A. Thom aptly referred to as "the everyday problems of the everyday child."

With this as a premise, Thom opened in 1921 the so-called Habit Clinic in Boston. In 1922, the National Committee for Mental Hygiene, fully 13 years after its foundation, was ready to institute the first child guid-

ance clinics, an organization which has since then become a nationally, and to quite an extent internationally, entrenched feature of communal policy.

These clinics soon became aware of an etiologic ingredient which had hitherto received but scant attention in the halls of formal learning. Those were the days when the markets resounded with the din of doctrinaire factions which, from separate booths, elevated the central nervous system, the endocrines, foci of infection, allegedly ubiquitous instincts and complexes, or supposedly innate typologic characteristics to the rank of all-valid explanations of human behavior. The child guidance clinics, in closer touch with homes and schools than any psychiatric unit which was then in operation, came to appreciate children as more than merely amebadlike creatures sending out their variously constituted pseudopodia into a more or less hazily structured environment. They recognized the dependence of early personality development on the impact of specific people in the environment. The investigations of parental attitudes and their effects may well be regarded as a great contribution made by these clinics not only to child study but also, in the general area of psychiatry, to a reorientation which began to include the varieties of interpersonal relationship in the range of etiologic and therapeutic considerations.

The organization of the clinics started out with a determined change from departmental isolation. The desire for multidisciplinary collaboration gave form to the "team" of psychiatrist, psychologist, and social worker, but this auspicious beginning, instead of serving as a lever for further broadening, was allowed to be frozen into a rigid mold. All disciplines other than those three were kept away from the clinic doors. As a result, before long the clinics were estranged from medicine, set admission age levels beyond the years of infancy, held the problems of retarded children to be outside the realm of their usefulness and, limited by these and other self-imposed restrictions, became another extremely valuable but nevertheless separate pile of building stones to go into the edifice of child psychiatry.

By the middle of the 1920's, there certainly was ample raw material lying around in different clusters and waiting for an architect to put it together. This task was carried out admirably by August Homburger of Heidelberg, who managed to house the thus far detached piles of building stones under one roof as closely interconnected parts of a unified structure. Homburger, on the faculty of a typically hyphenated neuro-psychiatric unit, was invited by his chief, Franz Nissl, to head an outpatient department. He brought with him a warm interest in children and quickly found himself in contact with pediatricians, educators, judges, and the personnel of child-caring institutions. He studied every aspect of childhood development and behavior and every available means of helping his patients. Shying away from the restriction to any one type of problem or method, he incorporated and integrated in his work and in his fascinatingly written book, published in 1926, the sum total of knowledge gathered from several sources. He, therefore, may be regarded as the first student, practitioner, and teacher of comprehensive child psychiatry devoid of sectional apportionment.

In this, Homburger stood alone for a while and, with a few exceptions, there was, at the time of his early death, still a prevalence of tubular vision in the nothing-but behavioristic, organicist, instinctivistic, or quasi-sociological approaches to children's behavior. All of them neglected an important group which, though exhorted to apply psychiatric understanding in dealing with children and chided for the lack of such understanding, was nevertheless denied passage through the portals leading to the acquisition of the proclaimed wisdom. Haughty pontification was apparently all that the pediatrician, the parents' first and foremost advisor, was thought to be good for. This is illustrated by the book, *The Child in America*, by W. I. and D. S. Thomas, a 1928 review of the studies and programs concerned with the behavior problems of children. The substantial volume dealt with the varieties of maladjustment, the treatment of delinquency, child guidance clinics, community organizations, parent education, and the contributions

made and planned by schools, psychologists, mental hygienists, and social workers, to the study, prevention, and treatment of early personality disorders. The authors, who spared no time nor space to cover the entire field, had no occasion anywhere to include the pediatricians as participants in any of these activities. In 1930, the Committee on Medical Care and Protection, in preparation for the White House Conference on Child Health and Protection, selected a special Subcommittee on Psychology and Psychiatry in Pediatrics. The beautifully worded conclusions expressed a plea for "psychiatrically intelligent doctors" but nothing was said about any practical arrangement which might teach doctors how to become psychiatrically intelligent.

In 1930, after a brief era of good-will oratory and get-together conferences, a psychiatric consultation service was set up at the Pediatric Department of the Johns Hopkins Hospital. The main objective of the task was presented as "an investigation of the rank and file of patients in the pediatric clinics for the formulation of psychiatric problems, the mastery of which should be made accessible to the pediatrician to serve him as the psychopathologic principles in dealing with children." Even though the avowed aim seemed to be one of carrying the torch of enlightenment to a group of more or less eager learners, the major advantage lay in the opportunity to test and demonstrate the usefulness of psychiatry in the main stream of a children's hospital. Selectivity on any basis was unrealistic and impractical in wards and dispensaries to which children came from every conceivable kind of milieu and with every conceivable kind of ailment. Under these circumstances, the liaison work had to comprise all aspects of a child's adjustment to living from birth through adolescence, associated with bodily diseases and anomalies, intellectual shortcomings, pathogenic parental attitudes, milder or more deep-seated emotional troubles, and a wide range of combinations. As similar undertakings began to be developed in the country sporadically, it became evident that here, in the hustle and bustle of busy medical centers, was a chance and an obligation to practice child psychiatry in the Hom-

burger sense, not as a compartmental preoccupation with intellectual deficit, scholastic problems, delinquent behavior, psychosomatic illness, psychologic and socio-economic deprivation, or neurotic and psychotic manifestations, but as a multifaceted discipline concerning itself with the overall responsibility for the amelioration of all and sundry difficulties presented by and to children referred for psychiatric assistance.

This does not imply in the remotest that such centers are, or should be, self-sufficient. They are by no means functioning as substitutes for the work done in the different rooms and cubicles of the edifice of child psychiatry. Their very existence would be unthinkable if it had not been for the separate efforts which furnished the foundation and the substance of the integrated structure. We still need, and should encourage, the expansion of child guidance clinics, which have proved themselves as indispensable pillars of community mental hygiene. Every effort should be made to provide adequate psychiatric counsel for our juvenile courts which still are, or at any rate should be, the principal adjusters of our delinquent youth. We should be sadly amiss if we did not acquaint ourselves fully with the truly breathtaking discoveries made recently in the area of mental deficiency. Child psychiatry continues to be enriched by advances made constantly in the fields of pediatrics, neurology, genetics, psychology, and sociology which keep adding to our knowledge of children in health and disease.

It is true that comprehensive child psychiatry, which has come into being less than half a century ago, is coming of age. It is true that this body of facts, theories, and practices, which did not even have a unifying name before 1933, has since then become accepted ungrudgingly as one of the scientific disciplines endeavoring to understand and help human beings. We are entitled to stand in awe before the vast amount of knowledge and insight that has been accumulated in so short a time. We child psychiatrists have formed our own clinics and have our own national associations and international congresses; very recently a subspecialty board has been

created, giving diploma recognition to qualified practitioners. Two leading universities have created full professorships of child psychiatry. The Royal Medico-Psychological Association has given formal status to child psychiatry by inviting one of its representatives to deliver the 1958 Maudsley lecture in London.

But, as in every science, last words have not been spoken and, considering the limitations of the species, the absolute and ultimate are beyond the horizon.* Having arrived, we are entitled to certain dissatisfactions with the extent of our achievements. Progress in every science depends on dissatisfaction, curiosity, and caution. It is those qualities that have provided the impetus for the introduction of ever new theoretical formulations, therapeutic avenues, research programs, and the improvement of residential facilities. It is those qualities that have prompted the work of the major contributors to child psychiatry.

Those qualities are still needed. There are still many gaps in our knowledge. This is no time for the smugness which pretends that we are already in possession of all the answers, that the sowing and planting have been accomplished, and that we are ready to sit back and enjoy the pleasures of eternal harvesting. Smugness can easily lead to stagnation. Some of us are too prone to surround the few kernels of truth with thick layers of as yet unproven hypotheses of one kind or another and, as teachers, to stifle the curiosities of our trainees by presenting these layers to them as established undisputable verities. If the teacher's speculations tend to be transmitted as articles of faith, theory and method are allowed to be frozen into rigid molds.

This pertains especially to certain treatment procedures. We are witnessing the spectacle of instruction which teaches a "technique" to be applied to all comers, regardless of the nature of the problems and the needs of each child as a unique experiment of nature. What happens to the treated patient is deemed by some less important than the niceties of the compulsive application of a learned technique. The therapist's minutely detailed "approach" to the diagnostically undifferentiated patient is considered as being of greater weight than the

specificity of the issue about which the patient and his family approach the therapist for help. The therapeutic cart is put much too often before the diagnostic horse. We would not think much of the surgeon who "approaches" an appendectomy, a thyroidectomy, and the setting of a broken leg with the same technique and the same instruments.

Fortunately for the future of child psychiatry, there are enough practitioners and teachers who are patient-oriented rather than technique-oriented, who pluralistically deal with the realities as they present themselves rather than with free-floating generalizations, and who whet their own curiosities and those of their students in the face of the multitudinous variety of issues that come before them. There is room for hypothesis, to be sure, but there is also an obligation to test every hypothesis for its scientific validity and its therapeutic effect. Treatment, under the circumstances, takes the form of an individualized, goal-determined program adapted to each child in accordance with his personal, carefully diagnosed, problem. This is different from the kind of stereotyped therapy which starts out as a journey into the unknown, with the vague hope that somehow, someday normalcy will be attained in the image of the therapist's concept of suburbanite propriety.

It is, of course, much easier to give a historical sketch of the development of child psychiatry than it is to outline its prospect for the future. But there are straws in the wind to indicate directions. There is a definite tendency to reduce compartmentalization and to hold the original piles of building stones together in units closely associated with medical centers. There is a growing realization of the need for increasing the number of residential treatment facilities for psychotic and near-psychotic children. Parents, impatient with the former laissez-faire attitude on the part of the medical profession have gotten together and, as the National Association for Retarded Children and the National Organization for Mentally Ill Children, have become a powerful influence, encouraging further investigations and

nudging legislatures into greater awareness of the situation. The National Institute of Mental Health is fostering both research and training.

In more circumscribed areas, much work has been done, and continues to be done, in the study of family relationship and its prophylactic and therapeutic utilization, the phenomenology and epidemiology of children's behavior problems, the diagnostic delineation of the more severe emotional disturbances, the biochemical aspects of certain forms of mental deficiency, the complexities of psychosomatic disorders, and

efforts, as yet timid and resisted by the insecure members of the group, to test the effectiveness of current therapeutic methods by means of follow-up studies.

The future of child psychiatry is bright. Its importance is now recognized universally. It has much to show for the short period of its existence. It will be brighter still if it manages to slough off a certain degree of smugness in its ranks, if it does not let its curiosity flag, if it keeps in mind that theory and technique are, for the physician, not ends in themselves but means to ameliorate the difficulties of patients.

SOME PROBLEMS OF DOSE VARIATION IN THE USE OF TRANQUILIZING DRUGS¹

BERNARD WILKENS, M.D., AND SIDNEY MALITZ, M.D.²

Because the implications of this title are broad and space does not permit an exhaustive account of all possible ramifications, this discussion is limited to the following:

1. A brief review of the development of dosage levels of tranquilizing drugs, with special emphasis on the prototypes of each group, namely chlorpromazine, reserpine and meprobamate.

2. A consideration of current dosages in use both in this country and abroad.

3. A brief summary of 3 cases illustrating some problems of dosage occurring in a clinical setting.

4. Some suggestions for developing a more scientific basis of dose range determination.

HISTORICAL ASPECTS OF DOSE RANGE DEVELOPMENT

Early workers with these drugs, unlike recent investigators, did not emphasize the effects of dosage range variation. Wilker (1) has published an excellent review of psychopharmacology in which the historical development of these drugs is discussed. The first medical application of a tranquilizing agent was for a non-psychiatric purpose. In 1951 the French investigator Laborit (2, 3) used chlorpromazine to prepare patients for major surgery. He attempted to induce a state of artificial hibernation with the drug that would decrease the total body metabolism, permitting patients to be refrigerated. Laborit, using doses of 50 to 100 mgm. I.V., noted no alterations in consciousness with the drug but rather a state of placid indifference

which he termed "a lobotomie pharmacologique." Determination of dosage appears to have been made on an empirical basis. Shortly after Laborit's reports, chlorpromazine was "discovered" by psychiatry, although there is no specific information on how the transition was made. Hamon (4) used chlorpromazine in 1952 in combination with meperidine in a patient with "mania." The dosages of chlorpromazine used were 50 and 75 mgm. I.M. Shortly thereafter, Delay and co-workers (5) also began to use chlorpromazine for mental disorders. The 6 patients of their initial series suffered from manic psychoses of various types. They emphasized the clinical effects of the drug rather than the dosage range. In two of the cases no dose is described. For two others, 50 mgm. q.i.d., I.M. and 75 mgm. t.i.d., I.M. is mentioned. In another, 25 mgm. I.M. in a single dose, and in the remaining, 100 mgm. orally. Later in a series of 38 patients, good responses were reported with chlorpromazine but again these investigators were not specific about the doses of medication that were used (6).

In 1953, Stahelin and Keilholz (7), in reporting on the treatment of a mixed group of psychiatric patients, described for the first time a detailed dosage schedule. They administered 25 mgm. of chlorpromazine I.M., 3 to 6 times daily. After 5 to 10 days they switched over to oral medication, in doses not exceeding 200 mgm. daily. They reported their results as generally favorable although no statistical data were given. Later, a number of other European investigators reported good results with chlorpromazine in the treatment of disturbed patients at levels averaging 100 mgm. daily which today is considered to be in the low dosage range.

About this time, several investigators in the United States and Great Britain began using chlorpromazine (8, 9, 10, 11). Again, as with European investigators, there was almost complete agreement on the clinical response and effects of the drug but con-

siderable variation in the reported dosage range. Table 1 indicates the dosage range

TABLE 1
CHLORPROMAZINE DOSAGE RANGE IN
SOME EARLY INVESTIGATIONS

Investigator	Dose Range/Day (mgm.)	Route
Elkes and Elkes	75-300	p.o.
Goldman	150-1800	p.o.
Hall and Dunlop	50-450	p.o.
Hoch and Malitz	300-400	p.o.
Kinross-Wright	200	I.M.
	200-4000	p.o.
Kurland	350-400	I.M. and p.o.
Winkleman	30-400	p.o.
Lehmann and Hanrahan	100	I.M.
	100-800	p.o.
Gibbs and Wilkens	75-450	p.o.

used by some early investigators of chlorpromazine. A few of these investigators tried systematically to isolate and measure the effects of chlorpromazine at various dosage levels by utilizing objective psychological tests(11a, 12, 13).

Chaptal in 1954(14) was the first to report using chlorpromazine on a mgm. per kg. body weight basis. It is of interest that he used the drug in doses of 2 to 3 mgm. per kg. for the treatment of "rheumatic and encephalitic chorea." Basmajian (15) in 1955 also used it in neurological disorders to decrease spasticity in single doses of 50 mgm. I.V. with favorable results.

The use of the whole root of *Rauwolfia Serpentina* is recorded centuries ago in the medical annals of India. However, isolation of some of the active crystalline alkaloids was not successfully begun until 1931 (16) and it was not until 1952(17), that reserpine, the most active of these alkaloids was identified. The pharmacological effects of reserpine in animals were studied in 1953 (18) and the sedative and hypotensive effects reported by a group of internists in Boston shortly thereafter. They administered the drug for the treatment of hypertension(19, 20). The first reports of reserpine as a tranquilizing agent in this country were not published until two years later (21).

Although many investigators have studied

reserpine, including several who used psychological techniques and physiological measurements, wide variations have existed in dosage range, routes of administration, duration of treatment, selection of patients and criteria for improvement, making valid correlative conclusions concerning their data difficult(21, 22, 23, 24, 25, 26, 27). Dosages in these studies have ranged widely from 1 to 130 mgm. per day.

Meprobamate belongs to a group of glycerol ethers which are motor depressants. Its precursor was mephanesin, discovered in 1946 and the first of this group used in the treatment of anxiety and tension states(28, 29, 30). Various analogues of this drug were synthesized, the most notable of which is meprobamate(31). Meprobamate was reported to have considerable clinical value in the treatment of anxiety states with dosages ranging between 400 to 1600 mgm. daily(32, 33). Alcoholics were treated with as much as 800 mgm. every 3 to 4 hours(33). It had also been reported successful in the treatment of chronic psychotic patients given 1000 to 5000 mgm. per day (34). One investigator reported using up to 9600 mgm. daily for periods of 12 to 18 months(35).

CURRENT DOSE RANGES

In recent years there has been a general tendency for physicians to administer higher average dosage levels of chlorpromazine and to a lesser degree reserpine. than were used when they were studied initially. Criteria for these changes, however, are vague. One group of investigators felt that the optimal dosage level should be higher in the more severely ill patients, and determined dosage as a direct function of the severity of the illness(36). Some emphasized the diagnostic category rather than the severity of the illness(35). Still others utilized the development and intensity of side effects such as parkinsonian symptoms in determining dosage level(37, 40). Thus it may be noted that a great deal of the subjective has entered into the use of these drugs. Considerably more research is necessary to clarify such issues.

In this country, dosage levels of chlorpromazine have risen from an average of 150 mgm. daily to a level of 300 to 500

mgm. daily (38, 39). Kinross-Wright (40) has continued to suggest higher average levels than most other investigators especially in the treatment of chronic cases. Ayd (41) on the other hand, feels that these large doses are no more effective than doses of 200 to 300 mgm. daily except in an occasional patient. Table 2 shows the cur-

TABLE 2

CURRENT AVERAGE DOSAGE RANGE OF
CHLORPROMAZINE IN VARIOUS COUNTRIES

<i>Country</i>	<i>Dose Range/Day (mgm.)</i>
England	150-300
France	400-600
Denmark	200-800
Switzerland (French)	200-400
Switzerland (German)	150-300
United States	300-500

rent average dosage range of chlorpromazine in various countries. It is possible that the lower dosages used in some countries reflect the innate conservatism of the citizens of that country!

Current therapeutic dosage levels of reserpine generally range from 0.1 to 5.0 mgm. daily orally (42). Occasionally average doses as high as 5 to 15 mgm. daily are recommended (43).

Present day therapeutic levels of meprobamate have varied very little from the more conservative early reports. The average dosage remains at 400 mgm. given 3 to 4 times a day.

ILLUSTRATIVE CASES

The following cases from the clinical service at Psychiatric Institute illustrate the types of therapeutic problems which have arisen in the past in relation to dosage levels:

Case 1.—A 31-year-old, white, male, clerical worker was first seen in the out-patient clinic in 1953. He was noted to be introspective, markedly voluble, loquacious and circumstantial. He complained of restlessness, headaches and somatic symptoms. He was followed at weekly intervals receiving psychoanalytically oriented psychotherapy. Psychological tests suggested a schizophrenic illness of long standing without intellectual damage. The patient

showed slight improvement during the early course of psychotherapy. After 3 years of treatment, however, he became increasingly agitated, developed a structured delusional system, auditory hallucinations and marked tension with anxiety. There was gross evidence of a thinking disorder. The patient was admitted to the Psychiatric Institute and given 50 insulin coma treatments resulting in a slight reduction in anxiety but no change in his basic symptomatology. He was then started on 300 mgm. of chlorpromazine a day. Within a period of 2 months, the patient became more coherent and there was a reduction in the tangential and circumstantial aspects of his thinking. His therapist felt encouraged and the dose was gradually increased to 1600 mgm. daily over a 6 month period. The improvement described disappeared on this higher dosage regime. The patient became increasingly tense, anxious and withdrawn. The dose was reduced to 800 mgm. without any change in his clinical condition. He was presented at conference to determine the feasibility of other forms of treatment. The patient was noted to show a moderately severe parkinsonian-like picture. Medication was discontinued so that a better idea of the baseline state of the patient, free from side effects could be gained. Over the next 2 months the parkinsonian features disappeared and he showed greater improvement than ever before. The anxiety and tension he experienced on high doses of chlorpromazine were markedly reduced. His original delusions and hallucinations did not recur. No evidence of disorganized thinking could be detected. The patient returned to work and was discharged to his own custody without further medication.

In this case the primary and secondary symptoms of schizophrenia, namely the thought disorder, hallucinations and delusions were reduced on low levels of the drug. Raising the dosage to accelerate the recovery intensified certain side effects of the drug which were then confused with symptoms of the primary disease process. The increased tension, restlessness and anxiety was thought to be a worsening of the patient's illness. Actually these symptoms were due to the drug itself and when the drug was discontinued they subsided.

Case 2.—The second patient was a 53-year-old, white, married, salesman with a history of multiple phobias and pan-anxiety for 7 years. The illness seemed to begin with an attack of vertigo and fears of being alone. Dur-

ing the 6 years preceding hospitalization the patient developed increasing phobias of closed spaces, heights, subway travel and losing his mind. During this period he was in psychotherapy on a twice a week basis and at various times received chlorpromazine, 150 mgm. daily, as well as reserpine and meprobamate in "low doses." He showed moderate improvement for a short time on the chlorpromazine but later relapsed. There was no response to the reserpine or meprobamate. Because of increasing pan-anxiety, panic attacks, agitation, referential ideas, multiple phobias, moderate depression and anhedonia, he was admitted to Psychiatric Institute with the diagnosis of schizophrenia, pseudoneurotic type. An attempt was made to control his symptoms with chlorpromazine. His dosage was raised to 1500 mgm. daily for a period of 3 months. Side effects were absent at this dosage level except for a slight parkinsonian picture. In spite of medication the patient continued to show an intensification of his original symptoms. Several other tranquilizers and somatic therapies were tried without success. A bilateral precoronal lobotomy was performed 6 months after his admission. Transient improvement in all symptoms was observed for two months. Then the patient relapsed. He received chlorpromazine once more in a dose ranging from 400 to 1200 mgm. daily for 2 weeks without benefit. No side effects were observed.

This case illustrates the surprising lack of side effects in some patients at high dosage levels on tranquilizing agents. It also, unfortunately, demonstrates that some cases, in which tranquilizers appear indicated, still do not respond. This man's anxiety and tension were so severe they did not even respond to psychosurgery.

Case 3.—A 55-year-old, white, male, married policeman was admitted to the hospital with a 5 year history of agitation, fearfulness, obsessive preoccupations, paranoid ideation, grandiosity and loquaciousness. A course of 9 electroshock treatments prior to admission had resulted in improvement lasting only 6 months. On admission, the patient's dosage of chlorpromazine was rapidly raised to a maintenance level of 600 mgm. daily. His talkativeness, grandiosity, delusional ideas and euphoria diminished considerably and he became manageable within a week. Troublesome side effects developed, however, including marked drowsiness, nasal congestion, constipation and moderate depression. The latter did not respond to the addition of amphetamine. After

4 weeks the symptoms gradually returned. He was started on reserpine in a range of 4 to 8 mgm. daily with little therapeutic effect over a 3 month period. A second course of chlorpromazine was given ranging from 600 to 1400 mgm. daily. At the maximum dose his symptoms again diminished but he developed severe side effects once more. After 2 months he relapsed. An intensive course of ECT failed to alter the pattern. Because of his assaultive behavior and rapidly worsening condition a bilateral precoronal lobotomy was done. A biopsy⁷ showed early Alzheimer's Disease. Following surgery, there was a quantitative diminution in all symptoms, but sporadic episodes of agitation and assaultiveness continued to occur. Chlorpromazine was given again over a range of 150 to 1400 mgm. a day in an attempt to control these outbursts. There was no effect at the lower levels but above 800 mgm. the patient became much less agitated and was finally stabilized at 1400 mgm. a day. He appeared more relaxed and less grandiose but his affect remained inappropriate and his associations impaired. A moderately severe parkinsonian syndrome developing at this level in no way affected his sustained improvement. Eventually this side effect cleared with the addition of Artane.

In this case, increasing the dose to therapeutic levels was associated with severe side effects accompanied by significant clinical improvement. The addition of an adjuvant drug helped to control the side effects so that it was not necessary to discontinue the phenothiazine.

These cases illustrate the recent trend towards prescribing tranquilizing drugs empirically. We feel that while the empirical approach is necessary in the opening of a new field of scientific endeavor, efforts should be continuously in the direction of reducing subjective factors. The question now arises as to how we can best proceed in our present and future evaluations of these psychopharmacologic agents.

RECENT APPROACHES TO DOSE RANGE PROBLEMS

Early studies of tranquilizing drugs were limited to the usual pharmacological battery of animal tests for toxicity and acute and chronic effects at graded dosage levels. In more recent years, laboratory methods used in the search for new psychopharma-

cologic drugs have undergone much refinement. Toman and Everett(44) list 6 standard and 14 alternate procedures that might be used. They point out that a battery of these tests in several species offers some insurance against missing a potentially valuable agent. These techniques are listed in Table 3.

TABLE 3

SCREENING METHODS FOR STUDY
OF TRANQUILIZERS

(Toman and Everett)

Standard Procedures

1. General screening in white mice, oral and intraperitoneal.
2. Potentiation of barbiturates.
3. Electroshock latency.
4. Body temperature control.
5. Spontaneous behavior in other species, single and multiple doses.
6. Chronic oral administration in dogs and rats.

Other Tests

1. Threshold and form of EEG in unanesthetized rabbits and monkeys.
2. Quantitative recording of limb tremor.
3. Body temperature of mice to warm and cold environments.
4. Recording electrically and mechanically evoked limb reflexes in rabbits.
5. Conditioned avoidance responses in rats.
6. In vitro tests on isolated uterus.
7. Blood pressure and respiration in anesthetized cat preparations.
8. Blood pressure response in experimental hypertensive rats.
9. Behavior after injection into ventricles of cats with chronic cannulas.
10. Quantitative recording of mouse motility in activity cages.
11. Biochemical tests of drug ability to release or reduce serotonin.
12. Stimulation of and recording from subcortical structures.
13. Assays in submammalian species or tissue cultures.
14. Tests for protection against drug induced emesis.

The question remains, however, whether such tests give a valid indication of therapeutic effectiveness of dosage level in man. The rat, cat, rabbit, dog and even the monkey represent such a wide species difference from man and his unique mental apparatus that it is difficult to correlate animal findings with the determination of human treatment dosages. It appears to us that the ultimate determination of correct therapeutic dose range must come from clinical, psychological and neurophysiological studies in man. Probably the single most important factor is clinical observation. Clinical observation may be correlated with batteries of objective psychological tests, double blind techniques, blocking studies of drug induced hallucinations, observations of electroencephalographic changes and other physiological measurements, but it cannot be subordinated to them. Specialized techniques are best performed on inpatients at a specialized research facility utilizing trained personnel. However, good clinical observations can be carried out in the usual clinical psychiatric inpatient or outpatient treatment setting.

The small clinical pilot study of 6 to 12 patients by experienced clinicians often contributes much to the evaluation of a new drug, especially in regard to factors of dosage and side effects. The value of such studies should not be minimized. We have had extensive experience with both blind and non-blind studies and have observed that the small pilot study has yielded accurate information not only concerning dosage levels but also relative to the spectrum of complications which were later confirmed by controlled studies of larger samples.

Such pilot studies as undertaken in our clinical laboratory are a joint undertaking of medical, nursing and social service staff under the personal supervision of the project physician. Diagnoses are established by a panel of psychiatrists and supported by psychological tests when necessary. The initial dosage schedule is established on the basis of the manufacturer's recommendations. A wide degree of flexibility must be permitted, however, to deal with any adverse side effects that might suddenly occur. It is sometimes necessary to lower or raise dosage levels markedly from the starting

dosage because of the individual variations in tolerance that are commonly encountered.

Before starting the active substance, a period of 7 to 14 days is devoted to observing the patient on placebo medication. Frequent and regular ward rounds are made, in which therapist, ward supervisor, nursing staff and social worker meet with those in charge of the project to discuss each patient's progress. The patients are followed personally by the drug project supervisor. An internist is part of the team to aid in evaluating and treating side effects developing as a complication of usage of new drugs. A battery of laboratory tests including hematological, hepatic and urinary procedures are performed before starting the drug, and repeated weekly. These include CBC, urinalysis, BSP, alkaline phosphatase, cephalin flocculation, BUN and fasting blood sugar. Ancillary studies including serial electroencephalograms and electrocardiograms are done whenever they seem indicated.

Cole, *et al.* (45) have elaborated on certain procedures that may be followed to improve clinical drug evaluation reports. They suggest that the dosage schedule and the variations be specified, and any technical problems of administration or facts regarding the duration of action be stated. Also they feel it is preferable that units of dosage be reported in the metric system, that route of administration, concentration and volume be recorded, and that effective dosage be expressed on a kg. per body weight basis whenever possible. Concentrations of the drug in blood and urine should be obtained when present techniques are sufficiently developed. We are in complete agreement with these aims. At the present time one of our co-workers has shared in developing a technique for the determination of phenothiazines in tissue and is engaged in working out a quantitative method for determining phenothiazine levels in the blood (46).

By following these procedures, the small pilot study becomes a carefully planned scientific instrument yielding data about drug action in the individual often missed in large scale clinical studies designed on a more casual observational program.

SUMMARY

Early published studies of the use of tranquilizers revealed wide variations in the methods of studying the clinical effectiveness of these drugs. Some studies omitted dosages used in arriving at conclusions regarding drug action. Others included dosage schedules but did not establish clearly the criteria on which these dosages were based. Generally the overall approach in these investigations was empirical. Currently, suggested dosage ranges of chlorpromazine, reserpine and meprobamate show a greater consistency than in the past.

Three cases are presented to demonstrate some of the clinical problems encountered in the administration of these drugs. They emphasize the necessity of focusing on dose range-clinical response relationships in future investigations.

The design of a small pilot study is presented. It is considered that this type of study offers the best opportunity to gain valuable information about dosage and drug effect when carefully and systematically performed.

BACKGROUND FACTORS AND SYMPTOM PRESENTATION IN A CHILD GUIDANCE CLINIC

FRANK G. BUCKNAM, M.D.,¹ AND MARVIN REZNIKOFF, Ph.D.²

In a recent study, Roach, Gurrslin and Hunt(1) investigated the social-psychological characteristics of families availing themselves of the services of a community supported child guidance clinic in the Buffalo area. It is not too often that a clinic stops to scrutinize the statistical material at hand from this viewpoint, which made the findings of this study particularly interesting. These authors underlined the fact that particular agencies and specific geographic areas have their own peculiar features and that they may be essentially unrepresentative samples of the population to which data obtained from them becomes generalized. As a consequence they envisioned their study as one in a projected series of independent investigations of separate agencies in different locales, providing data which could eventually be pooled and afford a basis for an overall systematic analysis of social-psychological variables in the utilization of mental health facilities.

The present research has a twofold purpose. First it is intended as a replication of the Buffalo study in a different setting, in line with accruing data from a number of potentially disparate sources as suggested by Roach, Gurrslin and Hunt. Secondly, it is an attempt to move beyond largely descriptive statistics and to ascertain whether associations exist between demographic characteristics and the specific nature of the presenting complaints or symptoms.

PROCEDURE

The sample cases comprised all families applying for psychiatric assistance to, the Children's Clinic of the Institute of Living, Hartford, Connecticut during 1957 and 1958. The clinic is a non-profit service offered to the residents of the Greater Hartford area. A very nominal fee is charged but no one is deprived of services because of an inability to pay. All information was ob-

tained from the parents in an intake interview with a social worker. In that occasional omissions and ambiguities occurred in the data, the total number of cases employed in the computations varied with the specific descriptive classification being investigated.

Six of the 7 characteristics evaluated by Roach, Gurrslin and Hunt were utilized in this study: (a) sex of child, (b) family size, (c) occupation of major wage earner, (d) race, (e) religion and (f) symptom. The seventh, desirability of residential area for each family, was omitted because information relevant to rating this characteristic was not fully available.

Data for making the appropriate comparisons between the clinic cases and Greater Hartford area population derived from United States census figures(2, 3).

RESULTS

Treatment of the data paralleled the methodology of Roach, Gurrslin and Hunt with chi square used to test for statistical significance. An examination of Table 1, reveals that there was a gross underrepresentation of girls in the clinic population ($\chi^2 = 33.70$, d.f. = 1, $P < .001$), in agreement with the findings of the Buffalo study. Contrary to the results of this prior investigation, however, the present study revealed no statistically significant difference between the clinic and the general population with regard to race. While the Buffalo clinic serviced a disproportionately small number of non-whites, the Hartford clinic had non-white applicants in numbers approximating their representation in the population as a whole.

Table 2 indicates that the clinic families, classified according to occupation of major wage earners, fell into a distribution which on an overall basis was not significantly at variance with the general population, though the individual category "semi-skilled worker" was notably overrepresented. By contrast the Buffalo facility had an underrepresentation of the semi-skilled group and

² Director, Department of Clinical Psychology, Institute of Living, Hartford, Conn.

TABLE 1
DISTRIBUTION OF SEX AND RACE IN PERCENTAGES OF CLINIC
AND HARTFORD AREA POPULATIONS
(N = 239)

Population	Sex			Race		
	Male	Female	Total	Whites	Non-whites	Total
Clinic	74	26	100	93	7	100
Hartford Area	48	52	100	96	4	100

TABLE 2
DISTRIBUTION OF OCCUPATIONS IN PERCENT-
AGES OF MAJOR WAGE EARNER IN CLINIC
FAMILIES AND HARTFORD AREA POPULATION
(N = 230)

Occupation	Clinic	Hartford Area
Profession and technical	10	10
Proprietors, managers, officials	13	14
White collar, clerical	18	19
Skilled workers	19	22
Semi-skilled workers	32	21
Unskilled workers	8	14
Total	100	100

a conspicuous overrepresentation of the professional and managerial classes with the total occupational pattern varying from the census population to a statistically significant degree.

From Table 3 it can be seen that the religious composition of the clinic population differs somewhat from the general population. This disparity approaches statistical significance ($\chi^2 = 5.72$, d.f. = 2, $P < .10$) with a disproportionately small number of Catholics and an over-large number of Protestants and Jews represented in the clinic group. This particular finding is in the same direction as the data obtained by Roach, Gurrslin and Hunt, but not as clear-cut in nature.

TABLE 3
DISTRIBUTION OF RELIGIOUS AFFILIATIONS IN
PERCENTAGES OF CLINIC AND HARTFORD
AREA POPULATION
(N = 229)

Religion	Clinic	Hartford Area
Catholic	47	58
Jewish	13	9
Protestant	40	33
Total	100	100

Data relevant to number of children in the clinic families is included in Table 4. As was the case in the Buffalo study, there is a gross underrepresentation of only children in the clinic sample and a strikingly high number of children with 2 or more sibs ($\chi^2 = 50.18$, d.f. = 2, $P < .001$).

TABLE 4
DISTRIBUTION OF NUMBER OF CHILDREN IN
FAMILY IN PERCENTAGES OF CLINIC AND HART-
FORD AREA POPULATION
(N = 238)

Number of Children	Clinic	Hartford Area
1	16	44
2	32	35
3 or more	52	21
Total	100	100

As a final step in this phase of the study the Hartford and Buffalo Clinics were compared for the prevalence of various types of presenting symptoms. A statistically significant difference in the distributions was obtained ($\chi^2 = 15.88$, d.f. = 5, $P < .01$). Table 5 reveals that in the Hartford clinic the initial complaint was more often aggressive behavior, though in both clinic groups this was the predominant symptom classification. There was also a larger number of mixed symptom patterns in the Hartford clinic population, while the Buffalo group contained a greater proportion of cases falling into the mental retardation category.

As mentioned previously a second purpose of this study was to ascertain whether significant relationships occurred between the presenting symptoms and the specific demographic variables studied. The data were analyzed in the form of a series of contingency tables—symptoms distributed within each of the descriptive categories taken individually.

TABLE 5

DISTRIBUTION OF PRESENTING SYMPTOMS IN
PERCENTAGES OF HARTFORD AND BUFFALO
CLINIC POPULATIONS

Symptom	Hartford	Buffalo
Aggressive	40	35
Nonaggressive	24	28
Somatic complaints	8	9
Mentally retarded	8	14
Mixed	19	10
Unknown	1	1
Total	100	100

Considering the symptom breakdown by sex, it was found that girls in the Hartford clinic sample had somatic complaints to a significantly greater degree than boys, though it is to be noted that this particular type of symptom occurred in a relatively small number of the total cases. Only 4% of the boys presented this symptom compared with 19% of the girls with this complaint. There were no other symptoms which were substantially more characteristic of one sex than the other.

When the presenting symptoms are distributed by race, the non-whites have a significantly higher incidence of difficulties in the aggressive category. The figures were 70% and 37% aggressive symptoms for the non-whites and white groups respectively. There were no meaningful relationships in other symptom categories.

With respect to the symptoms by occupation distribution, non-aggressive presenting complaints characterized the upper three occupational grouping while symptomatic aggressive behavior was associated with the three lower occupational classifications. For the aggressive symptom category the average of the upper three occupations was 27% occurrence in contrast to 47% for the lower three classifications. It is worth pointing out that there is a gradual rise in the incidence of reported aggressive symptoms as one proceeds down the list of occupational titles, with the extremes being 9% for the professional technical group and 55% for the unskilled workers. The incidences for non-aggressive presenting symptomatology run in a reverse direction, but not quite as consistently, with the upper three occupational classes averaging 34% and the lower groups 18%. The other types of symp-

toms did not show any particular kind of ordering with occupation.

An appraisal of symptoms by religious affiliation and then by number of children in the family demonstrated no significant associations. This suggests that the kinds of symptoms reported in the present population are grossly independent of these factors.

DISCUSSION

The disparities between the findings of the present study and those of the previous investigation lend convincing support to the notion advanced by Roach, Gurrslin and Hunt that meaningful evaluation of social-psychological factors in the utilization of mental health facilities must subsume a number of separate samples from different agencies in varied locations. The dangers inherent in extending the findings of a single agency are immediately apparent in the comparison of the Hartford and Buffalo clinics.

Roach, Gurrslin and Hunt concluded that the population serviced by the Buffalo clinic could be characterized as "middle class." One immediate conclusion from the present findings as compared with the Buffalo clinic might be that the Hartford facility served a wider segment of the population, in the sense that no one class of patient seemed to predominate. The underrepresentation of Catholics and overrepresentation of Jews and Protestants deviated less from the population figures than had been the case in the other clinic. Non-whites were present in the Hartford clinic case load in proportion to the general population and the only occupational classification out of line with expectation was the semi-skilled group. The disproportionately large number of males served is a finding which is probably true of almost all the clinics throughout the country and may reflect a relationship between the tendency for parents to be most concerned about aggressive symptomatology and the inherently more aggressive role that is typically fostered in the male. The reason for the significantly small number of only children brought to the Clinic is not immediately apparent. It could conceivably result from the generally greater financial resources available for treatment in families

with one child, and their consequent preference for private therapy.

In endeavoring to interpret the associations between demographic variables and symptoms, the occupational background findings suggest that the professional and white collar group with their better education and greater psychological sophistication are apt to be more alert to the occurrence and seriousness of withdrawal symptomatology which might pass unnoticed or be considered unimportant by the lower middle class or working group. It might also reflect that the type of home environment and value system of families at the upper economic levels could contribute to a partial inhibition of destructive, acting out behavior in the children and a commensurately greater prevalence of seclusive symptomatology. The significant association between race and aggressive symptoms could be taken to mean that the non-white population as a result of long exposure to discrimination and prejudice is sensitized to having their children show any aggressive behavior. That is, that which might be taken as normal aggressive behavior in a white child is considered deviant in a non-white child since it will likely cause him difficulty in adjusting to his low status in our society. It could be hypothesized, therefore, that non-white families would be prompted to bring children with an aggressive symptom picture to the clinic comparatively more readily than white families.

SUMMARY

The study undertook to evaluate the kinds of family utilizing the services of the

Children's Clinic of the Institute of Living. In line with the previous investigation of Roach, Gurrslin and Hunt, 5 demographic factors were examined in 239 clinic patients. These were (a) sex of child, (b) family size, (c) occupation of major wage earner, (d) race and (e) religion. In addition, an effort was made to categorize presenting symptoms. The distribution of each of these descriptive characteristics in the clinic population was compared with census figures for the general population of the Greater Hartford area. The pattern of presenting symptoms found in the Hartford Clinic was contrasted with the results of the previous study. An effort was also made to determine whether these factors and the various kinds of presenting complaints were related in any way. It was found that the Hartford Clinic group did not always conform to general population expectation, particularly with respect to composition by sex, and number of children in the family and also differed from the Buffalo clinic. Statistically significant associations were obtained between occupational level and race and the symptom categories subsuming acting out and social withdrawal types of behavior.

A CHILDREN'S UNIT IN A STATE HOSPITAL

N. E. STRATAS, M.D.,¹ AND K. T. SCHMIDT, M.D.²

Beginning with work with mental defectives and, in courts, with "juvenile delinquents," the history of child psychiatry has moved through child guidance clinics and more recently to specialized children's residential units. However, a large portion of children's work remains in the sphere of the state mental hospital, especially in states where there are no other large inpatient treatment centers. This article describes a unit set up in a state mental hospital, for patients under the age of 18.

Originally at Eastern State Hospital, children were placed on adult wards with no effort to group them; however, about 4 years ago it was decided to group all boys and all girls under 18 in 2 separate wards. At first these wards were in separate buildings and were taken care of by a doctor who was also assigned other wards. There was very little extra activity planned for the children but enough improvement was noted to bring the two groups together in one building and to create several activities. Recently a more intensive program with a substantial staff has been directed at the unit with gratifying results.

Although objections have been raised in the past to locating a children's unit at a state hospital because of the supposed stigma involved, we find that this problem has greatly diminished as the staff, the parents, the children, schools and social agencies, establish a better relationship.

Admission to the unit is by the usual procedures of admission to a state hospital. However, seldom is a child committed as mentally ill, but rather, as a 45-day-care admission which is changed to voluntary status if further hospitalization is necessary. As well, the courts send many children for evaluation and therapy if necessary.

Our policies are based on fairly simple philosophical and psychological tenets; there is a general attitude of acceptance, warmth and understanding. We feel that in

view of the child's experiential world to date, he is entitled to be as he is, unhappy, and disturbed. At the same time we feel that certain limits are necessary as a basic frame of reference and a baseline of values. The child may not infringe upon the other children, the staff or upon the physical property.

Our object is to enable the children to return home; to help them to improve sufficiently to be placed in as near normal a situation as possible, and there to be followed on an outpatient basis by local clinics, or privately by psychiatrists or psychiatrically-oriented general practitioners.

The unit is under the direction of a physician-in-charge with previous psychiatric experience. He does the overall planning for the unit, sets policies and outlines the schedules. He is almost always available to staff members and has weekly meetings, with everyone involved in the unit and as well, with each department. In this way we attempt to derive a good interdepartmental relationship, alleviate anxiety of staff members accruing from their jobs and discuss any contrary opinions and procedures. The physician-in-charge admits the children, examines them physically and psychiatrically, orders necessary tests, assigns the children to groups and activities, and orders and supervises or conducts various forms of therapy. He in turn is closely supervised by our consulting child psychiatrist.

The 2 wards (capacity of 27 each) are L-shaped with the bedrooms along the long part of the L, and a smoking room and an alcove with 6 beds in the short part. Where these two parts meet there is a day-room, with lounging chairs, television, radio and record player. Centrally, the two wards merge into an area that contains the doctor's office, the nursing office, the treatment and examining room, the psychologist's office and the school rooms. In the basement are the recreation room and the occupational therapy shop.

Behind the building is an enclosed court

¹ Assistant Chief of Service and in charge of the Children's Unit.

² Clinical Director, Eastern State Hospital, Williamsburg, Va.

yard with facilities for outside games. In front is a large lawn area for basketball and baseball. To the right of the building is a woods with a small stream which is easily accessible.

The intellectual range of the children is usually average, with a substantial number at both extremes of the scale; their diagnoses vary from the mildest adjustment or behavior problems to very severe psychotic problems. The patients we receive are primarily mentally ill but multiple problems are involved; deficiency, organicity, personality disturbance, *etc.*

The children are divided into 4 groups, according to age and achievement levels, and participate in the program as groups, while at the same time attention is given to individuals in each group, for which a basic program is scheduled. The programs are fairly structuralized but pliable enough to allow for group and individual variation as needed. The program is set up so that therapy, school, and activities are incorporated. There are regular group therapy sessions for each group as well as individual therapy, play therapy, supportive therapy, superficial and deeper psychotherapy and hypnotherapy. The psychology department is actively involved in the therapy program under the direction of and assisting the physician.

One of the psychologists works full time in the unit administering tests as well as assisting in therapy. Each child that comes into the unit receives a thorough psychological evaluation, which assists in making diagnoses and in directing therapy.

The nursing personnel are very important members of the unit, both physically and therapeutically. The attendants are both male and female and very commonly find themselves in the roles of parental figures.

There are 3 full-time and 3 part-time professional teachers. The groups are small enough, 6 to 9 in each, to permit individualized attention and teaching. The school is designed to help develop creative patterns of behavior, to stimulate interest in learning and where indicated to maintain scholastic achievement sufficient to allow the child to return to his own grade when he is released.

The school also conducts educational

trips, a school newspaper written and edited by the students, weekly dances, and regular bus and station wagon rides.

The occupational therapy projects are aimed at motivating an interest toward activity, or offering the aggressive children a release in a socially acceptable fashion. The O. T. department could be of even greater value by including pre-vocational training, particularly for children who will not continue schooling after leaving the hospital. This department also sponsors roller-skating, swimming and bowling in the community facilities and softball, movies, *etc.*, on the hospital grounds. There is also an active music therapy division.

Insofar as management is concerned, we find that the permissiveness within limitations of a group structure, common to everyday living is very satisfactory. Problems are usually handled by restriction of activities or deprivation of privileges. Acute situations, as when a child becomes recalcitrant or harmful to others, have to be handled immediately and at times in a forceful manner. Then it may become necessary to remove a child bodily to his room. When a child begins to feel that he will overstep the simple limits or become quite upset, he is encouraged to go to his room until he feels ready to rejoin the group. Furthermore, immediate attention is given the child in such situations in the form of what we call psychiatric "first aid." We attempt to make it clear that discipline is not associated with rejection, and contact with the staff continues even when activities are restricted.

Although the wards are closed wards, unsupervised outside privileges are given to as many of the children as possible, and this has the effect of creating an open ward atmosphere. Since the establishment of a stepped-up program of outside privileges, carefully administered, there have been no attempts to leave without permission, whereas these were occasional occurrences previously.

Further in management we are greatly aided by a form of self-government. Two boys elected by the boys and 2 girls by the girls act as a council which meets with the physician once a week. Here, matters of a non-medical nature which involve the chil-

dren are discussed, and very often suggestions they make are adopted. Many times disciplinary measures are submitted by this group which are quite in proportion to the misdeed and so a form of self-discipline is encouraged.

The children freely correspond with friends and relatives and are visited frequently. The parents or foster parents meet with the physician about twice each month when they are allowed to ventilate and an attempt is made to give them some insight into the situation as a whole. At present, plans are being formulated to

bring the parents together in group therapy sessions.

SUMMARY

We have attempted here to describe a children's unit as it is in operation. We hope we have made it apparent that, although many arguments can be found against establishing children's units at mental hospitals, still while we continue to have children admitted to these hospitals, by grouping them and using facilities already present, with effective organization and management, basic present needs can be fairly well satisfied.

CASTE AND MENTAL HOSPITAL ADMISSIONS IN MYSORE STATE, INDIA

UMA SREENIVASAN, M.B.,¹ AND J. HOENIG, M.D.²

In India the caste system has always attracted the attention of observers. Caste is an exclusively Indian phenomenon, which provides every member of the caste with a system that controls his behaviour and his profession, his marriage and his friends and his birth and death rites. Several studies have been made of the relationship between psychiatric illness and caste, but few have been based on systematic research.

This paper gives an analysis of certain factors extracted from the case records of all the admissions to the Mental Hospital, Bangalore, Mysore State, in 1953.³ The influence of some other of these factors on admission rates has been considered elsewhere(1). In this report, a feature of special interest, namely caste, is considered in detail.

CASTE

Caste is not found outside of India, though social institutions analogous to caste have been described elsewhere in the world. One example is the development of plural societies, which come about through the conquest of one people by another of different race, producing a class of half-breeds with the passage of time, while the conqueror, conquered and half-breeds remain as three segregated classes. Other examples are economic and occupational institutions such as hereditary serfdom, aristocracies, social stratification according to wealth and so on. In fact the resemblance between caste and such analogous institutions is slight.

The English word caste is derived from the Portuguese word *casta*, meaning breed,

race or kind. It is easier to describe the features of a caste than to define it and most authorities would agree with the following description: A caste is a social unit in a system of segmental divisions of society. Birth determines a person's caste for life unless he be expelled from it for violation of caste rules. There is hierarchical graduation of castes, with the Brahmins at the top and the "degraded" untouchables at the bottom; the intermediate castes dispute among themselves as to their status in the hierarchy. Members of a caste cannot marry outside it. There are similar, though less rigid, restrictions on eating, drinking and social intercourse, with minute rules as to what sort of food and drink can be accepted and from what castes and what physical distance should be maintained between people of different castes. There is segregation of castes within the villages which goes hand in hand with civil and religious restrictive rules and privileges for different sections. There are fixed occupations for many castes. Although no one can change his or her caste during life, salvation is hoped for in the form of rebirth in a higher caste. The whole system turns on the prestige of the Brahmin; his presence "sanctifies" while the presence of the untouchable "pollutes."

Matters are, however, very much more complicated than would appear from this simple description. The statement that there are 4 castes in India: Brahmins (priests), Kshatriyas (warriors, kings), Vysias (merchants, traders) and Sudras (farmers, workers) is a gross over-simplification. Hut-ton(3) has pointed out that the stability of the caste system has been reinforced by the multiple and diverse origins of the people who compose it. It is believed that there are about 3,000 different castes and sub-castes in India while the census lists 57 main castes in Mysore State alone. Invasion, migration, race, colour, language and occupation have all played a part in originating the various sub-castes.

Castes and sub-castes mostly conform to

¹ Alder Hey Childrens Hospital, Liverpool, formerly Hon. Research Assistant, All India Institute of Mental Health, Bangalore, India.

² Senior Lecturer, Manchester University, formerly Visiting Professor, All India Institute of Mental Health, Bangalore, India.

³ Our thanks are due to Professor M. V. Govinda Swamy, Director of the All India Institute of Mental Health, for his invaluable help. We also wish to thank Shri Gopinath and also Male Nurse Shri Ramaya for their most valuable assistance.

the description given above, but some sub-castes are strictly exogamous. Again, two people of the same caste, who belong to different linguistic groups, usually cannot marry and may even observe taboos on eating and physical contact. Although the caste system has religious sanction from the priesthood only in Hinduism, the caste system affects members of other religious groups. Muslims, for example, who do not recognise the validity of the caste system often observe its taboos in practice; converts to Christianity, even in later generations, often retain their original caste for purposes of marriage. In Cochin the Jewish community is segregated into "White," "Brown" and "Black" Jews. The White Jews claim to be the "pure" descendants of migrants in the second century and regard the others as descendants of renegades by marriage or of converts and forbid them entry into their synagogue. Other taboos similar to caste taboos exist between these Jewish communities.

Complications are provided by exceptions to almost every rule; by occasional transition from one caste to another, by religious sanction for hypergamy between sub-castes, *etc.* In addition, representations to the authorities by some communities to have their status stepped up in the official records, have been occasionally successful. For instance, the Viswakarma (fishermen community in Mysore State) requested the Census Office that they should be counted among the Brahmins.

The large number of "untouchables" are now officially called "scheduled" or "depressed" castes, and form 15-25% of the population in different parts of India. The ideas of untouchability and unapproachability appear to have been first applied to the aboriginal tribes and later extended to other groups because of the theoretical impurity of certain occupations, such as scavenging, washing, fishing, *etc.* (4). The numbers have been added to by people who were expelled from a caste. A person may be out-casted for violating particular caste rules or the ethical code of religion. Thus adultery in a Nambudari (Kerala Brahmin) woman was punished by outcasting; killing a cow for most castes results in the same procedure; marriage between members of

exogamous communities results in the higher caste, and often the lower caste as well, disowning the couple, and formerly a Brahmin who failed to arrange his daughter's wedding before she attained puberty was outcasted. Even among the "scheduled" castes there is a hierarchy based on occupation.

There are also many splinter religions and sects which have usually originated from zealous reformers of the Caste System. In the course of time these have become very much like new castes of their own. Examples are the Lingayat Community in Mysore State and more recently, the Arya Samajists.

It is worth mentioning certain aspects of the Caste System which are of particular interest and value from the point of view of psychiatric research. Prior to the invasion of India by the Aryans in 1,500 B.C., the matrilineal system is believed to have been widely prevalent. This system is still accepted in Kerala and the customs associated with it survive to varying degrees all over South India. The influence on marriage customs is most pertinent. Among many castes in South India it is the prerogative of a man to marry his sister's daughter. This would be regarded as incest in North India. In Mysore State, the Vokkaligas and Lingayats, who form the major part of the population, favour uncle-niece marriage. The Brahmins regard it as unethical theoretically, but often practise it. In regard to cousin marriages restrictions vary according to caste and locality. Only cousin marriages between the children of a brother and sister are allowed. Marriage between the children of two brothers or two sisters is strictly forbidden to all Hindus. Cousin marriage is often the choice in South India, where again the practice is now quite common among Brahmins, the older of whom consider it an undesirable lapse.

In other parts of India the rules of consanguinity prohibit marriage when there is a common ancestor within the memory of either parent. Rare exceptions to all these rules are to be seen, such as social sanction to marry a half-sibling or to marry a grandchild. The practice of polyandry also occurs. Such practices have been made illegal since India has attained independence and are becoming increasingly rare. Polygamy

was legal until recently and is still practised. Legal sanction for divorce is even more recent, although forms of divorce have been present among certain castes for many years. It will be seen that there is a rich field here, not only for further studies of psychiatric disorders, but for more precise investigations into the cultural factors alleged to contribute to psychiatric breakdown. The immense variety of different social structures within a given geographical area offer an opportunity for comparative studies of incidence, prevalence and interaction with social factors not easily paralleled elsewhere.

THE HOSPITAL

This 300-bed mental hospital, which contains up to 550 patients, stands in a pleasant garden on the outskirts of the city of Bangalore. There is strict segregation of the sexes in all the activities of the patients, as custom demands. The hospital is the only inpatient unit for psychiatric patients for the whole of Mysore State⁴ with 9,079,972 inhabitants covering an area of 29,489 square miles. Distances are enormous and transport facilities poor, so that the hospital renders more service to the nearer areas. Acutely disturbed patients, in fetters, often travel to the hospital in turn by bullock carts, horse carts, on foot and by bus for many miles.

As a teaching institution the hospital enjoys an excellent reputation, and patients come from every part of India. In 1953 the hospital admitted a total of 948 patients of whom 137 were from outside Mysore State. We are concerned here only with the 811 patients admitted from Mysore State.

METHOD

We have used the official hospital case records for obtaining information about the patients. Information about the State of Mysore was taken partly from the Official Census of 1951 and partly from an interim census conducted in 1946. This became necessary because the Indian Government in 1951 discontinued the practice of previous censuses to break down population figures according to caste. Our figures on caste, therefore, were obtained from the

1946 census. In any case there is no reason to believe that the figures for 1953 would be materially different.

Of the 811 patients under consideration, 60% were men and 40% women. The first-admission rate was 7 per 100,000 of the population. The figures are very different from those obtained, for example, in England, and Wales where they are 97 per 100,000 population. The possible explanations for such differences and certain other factors, have been discussed elsewhere(2).

RESULTS AND DISCUSSION

The complexities of the caste system as outlined impose limitations on any conclusions which may be drawn from the information in the case records. Nevertheless the available figures are interesting.

Figure 1 shows the percentage of the main religious communities and castes in the general population and their admission rates. The Hindus who form 74% of the population, have the lowest admission rate. The differences in admission rates of the castes are striking. The Vaisyas are leading with 55 per 100,000 of the population, the Brahmins with 42 per 100,000 follow close, while the Kshatriyas with 15 per 100,000 while still well above the average for the Hindus, show a considerable drop. These 3 castes, in all, provide only 7-8% of the population. The Sudras and scheduled castes, on the other hand, form the greater part of the total Hindu community, but their contribution to the mental hospital admission rate is insignificant.

After the Vaisya and Brahmin castes, the Indian Christian community, although only 1% of the population, has the third highest admission rate with 31 admissions per 100,000 of the population. The other two minority communities, Muslims and Jains, have admission rates of 13 and 12 respectively. Jainism is an offshoot of Hinduism and originated in the 5th century B.C. at about the same time as Buddhism. In Mysore State the followers of this religion form 1.5% of the population. Most Jains live in other parts of India.

These figures have probably not much bearing on the actual incidence of mental illness in the respective communities. It would be interesting therefore to know why

⁴ Before reorganisation of the States in 1957.

FIGURE 1

GRAPH SHOWING THE RELATIVE SIZE OF THE COMMUNITIES,
AND THE ADMISSION RATE FOR EACH COMMUNITY.

the admission rates are so varied. Information on factors which might be presumed to influence admission figures was not available in the case records in any degree of precision. We therefore had recourse to the official census of 1946 for figures on aspects of the castes and communities which might throw light on the admission figures. Two factors are presented here which appear to be relevant. These are the distribution of literacy and the percentage of population in the different communities living in cities.

Literacy was briefly defined in the census as "a person's ability to read and write a letter" and assessed as such among the population, with reference to caste and community. No enquiry on this score had been made among the patients admitted to the hospital.

Figure 2 shows that some correlation exists between literacy and admission rate of each community. A higher percentage of literates in the community appears to be associated with a higher admission rate, but there are slight discrepancies. Thus the Vaisyas, with an admission rate of 55 per 100,000 of the population, should have the highest rate of literacy, but in fact, they have a lower rate of literacy (44%) than the

Brahmins (58%). The Brahmins have an admission rate of 42 per 100,000 in the population, and the highest percentage of literates among all the communities (58%). The Sudras with 11% literates and the depressed castes with 4% literates show the same discrepancy with regard to admission rates, but the figures are very small. The Indian Christian community with 36% literacy have appropriately the third highest admission rate. Between the three more literate communities on the one hand and the largely illiterate communities of Sudras and depressed castes on the other, the Kshatriyas, Jains and Muslims more or less conform to the pattern.

Figure 3 shows the percentage of literates in the different communities as they vary between the three cities and the rest of Mysore State. Three cities with 19.3% of the total population contributed 48.7% of total new admissions to the Mental Hospital in 1953. For the whole of Mysore State the literacy rate is 35% in the cities and 11% in the districts. Brahmins have a literacy rate of 69% in the cities and 55% in the districts. With these figures they have the highest literacy rate in Mysore State. Owing to non-specification in the census on this matter,

FIGURE 2

GRAPH SHOWING THE DEGREE OF LITERACY AND THE INCIDENCE OF ADMISSIONS IN VARIOUS COMMUNITIES.

FIGURE 3

GRAPH SHOWING LITERACY PER 100 POPULATION IN EACH COMMUNITY.

we have unfortunately been forced to give the figures for Vaishyas, Kshatriyas and Sudras as one group i.e. "other Hindus." The Jains show a strikingly high literacy rate in the cities with 59%, the rate for the districts being only 26%. Two other groups show a similarly marked difference between literacy rates in cities and districts: the depressed classes with 14% and 2% respectively, and the group "other Hindus" with 30% and 10% in cities and districts respectively.

TABLE 1

Community	Residence	No. of Admissions	Admission Rate per 100,000 Population
All Hindus	Cities	181	26.8
	Districts	194	3.1
Brahmins	Cities	70	92.5
	Districts	35	16.5
Vokkaligas (Largest Sudra Caste)	Cities	15	14.3
	Districts	61	4.6
Adikarnatakas (Largest scheduled caste)	Cities	9	6.7
	Districts	7	0.7
Muslims	Cities	18	11.6
	Districts	22	5.2
Indian Christians	Cities	15	11.9
	Districts	2	3

In Table 1 the admissions to the mental hospital from the 3 cities together are compared with those from the districts, showing the communities separately. As the census reports unfortunately do not give the relevant figures for all castes, only certain communities can be shown in this table. The table includes only those admissions to the hospital who were voluntary or certified. Cases admitted for observation had to be excluded as the address entered on the case records is usually that of the referring law court instead of the domicile of the patient.

All the communities shown in Table 1 have a much higher rate of admission from the cities than from the rest of Mysore State, although, as stated before, only 19.3% of the population is accounted for by the cities. The figure for all Hindu admissions

from the cities is 9 times higher in comparison to the admission rate from the districts. The same is true of the Adikarnatakas who are the largest subdivision among the depressed or scheduled castes. The Brahmins follow next with an admission rate 6 times higher from the cities. The Vokkaligas, a peasant community form the major sub-caste of the Sudras. They and the Christians have each an admission rate 4 times higher in the cities. Muslims are only twice as frequently admitted from the cities. The figures for Christians are not really applicable as Europeans and Anglo-Indians are also included in the population figures. These 2 groups tend to live almost exclusively in the large cities. A greater discrepancy between the admission rates for city and district areas seems to be present among those communities in which a very small minority live in city areas, though this is not entirely borne out when one compares the population figures for the Vokkaligas and Brahmins. Inaccuracies in reporting in the case records may account for this. Unfortunately, figures for the number of Vaisyas resident in cities as distinct from districts were not available. They form a small community of traders and merchants and it is possible that the proportion of Vaisyas living in cities would be high.

A few conclusions may perhaps be drawn from these figures. The minority castes and communities have a higher rate of admission to the mental hospital in Mysore State than the majority castes. Literacy and residence in cities would seem to be factors which correlate with these higher admission rates. One can only hazard a guess why this should be so. Considering the difficulties in transport, facilities for admission are much better in cities. Both residence in cities and literacy would enable individuals to be more familiar with the hospital services available. As a result, confidence in hospitals and willingness to use these facilities are usually greater in the city dweller. The figures are inviting for more far reaching speculative explanations. But we feel that without further more detailed research such explanations cannot really be held with any confidence. It is perhaps interesting to compare the situation with that reflected by recent Western studies, where the higher ad-

mission rates correlate with the larger, less educated and less skilled classes, and urban rates tend to be higher than rural.

CONCLUSION

We are mainly concerned in this paper to highlight the potentialities and necessity for further research in psychiatry in India. Indisputably the caste system exerts a profound influence on every aspect of life in that country. Certain castes, notably the Brahmins and Vysias show a higher admission rate to the mental hospital than others, but further research would be required before one could account for this with confidence. It would also be interesting to know what is the actual incidence of mental illness in the different communities. Does a higher admission rate from the cities signify a higher incidence of mental illness resulting in some way from urbanisation and industrialisation or does it merely reflect the social factor of availability of care? From our experience of villages near Bangalore City it would appear that there are a great many people in rural areas with fairly severe forms of mental illness who have never been near a mental hospital.

Opinion to date is still divided on the extent to which heredity and environment influence the development of mental illness. In this respect the state of affairs in Mysore State should prove a most fruitful source of research. Various forms of inbreeding for generations are present, along with forms of strict exogamy. In addition, the segregation of castes and the variety of cultural factors seem to present us with an experimental situation already in existence.

SUMMARY

A brief outline is given of some features of the Indian caste system which may be of interest to social psychiatry. The case records of the mental hospital in Bangalore have been analysed in relation to caste of the patient and the results correlated with certain caste data in the Census reports of Mysore State. It was found that certain castes or communities like the Vysias, Brahmins and Indian Christians show a higher admission rate than other castes. It was also found that the cities of the state show a higher admission rate than the rural areas. The castes and communities which show high admission rates show a higher degree of literacy. Within each caste or community literacy is also higher in the cities than in the rural areas.

The general situation in India offers great opportunities for fruitful research in social psychiatry.

The significance of these facts and their relation to the true incidence of mental illness awaits further research, both genetic and environmental, for which the caste structure of India offers great opportunities.

A PSYCHIATRIC CENSUS OF THE SOUTH PACIFIC

ERIC BERNE, M.D.¹

The following figures include the important political divisions of what is commonly known as the South Pacific. They comprise the area lying between the Equator and 30 deg. S. latitude, and 135 deg. E. to 130 deg. W. longitude, which takes in with a few minor exceptions, the whole of Melanesia and southern Polynesia. The Gilbert and Ellice Islands are not included because anthropologically they belong to the more northern Micronesians.

The figures for New Zealand and Tasmania, which lie a little farther to the South, are appended for reference. The figures refer to conditions as of June 1, 1958. Those for "Patients" refer to psychiatric patients only. Those for "Population Served" are supplied by the local Medical Officers and do not necessarily correspond to the official census figures.

DISCUSSION

1. *Prevalence.* Table 1 tends to indicate that the apparent prevalence of psychiatric disorders is a direct function of the facilities offered for diagnosis and treatment, a principle which the writer has previously enunciated(1).

First, as to diagnosis, the apparent preva-

lence bears a rather direct relationship to the number of practitioners with medical training in each area. For example, in the British Solomon Islands, where there were 5 medical officers and 15 assistant medical officers(2) for a "Population served" of 112,000 (1/5600), the apparent prevalence of psychiatric disorders was 1/16000. In Papua-New Guinea, where there were 91 medical officers(2) and approximately 1,400 assistant medical officers (1/1220), the apparent prevalence was 1/3050. Thus in the area where there were about 5 times as many practitioners, the apparent prevalence was about 5 times as high. These ratios do not form a linear series throughout the area, but the tendency is sufficiently well marked to be impressive. Western Samoa falls about midway, with 4 M.O. and 40 A.M.O. for 108,000 people (1/2270) and an apparent prevalence of 1/8333.

Secondly, as to treatment, those areas which have special hospital facilities for psychiatric patients (excluding New Zealand and Tasmania) have an aggregate population served of 2,827,000 (A, B, C, D, F, J, K) and an aggregate estimated patient census of at least 1,410, yielding an apparent prevalence ratio of about 1/2000. Those areas which have no such facilities (E, G, H, I) have an aggregate population

TABLE 1
APPARENT PREVALENCE IN U. S. A. 1/200-250

Area	Patients in Hospitals	Estimated Patient Census	Population Served	Apparent Prevalence
A. Dutch New Guinea	45	90+	350,000	1/3900
B. Papua-New Guinea	26	600	1,830,000	1/3050
C. British Solomons	7	7	112,000	1/16000
D. New Caledonia	96	96+	70,000	1/730
E. New Hebrides	8	20+	52,000	1/2500
F. Fiji Islands	172	558	375,000	1/670
G. Tonga	6	30	58,000	1/1900
H. Western Samoa	5	12+	100,000	1/8333
I. American Samoa	3	8+	21,000	1/3500
J. Cook Islands	2	4-5	17,000	1/3500
K. French Oceania	12	57	73,000	1/1300
L. New Zealand	9,848	10,728	2,200,000	1/205
M. Tasmania	1,030	1,144	336,500	1/294

¹ Box 2111, Carmel, Calif.

served of about 231,000, with an estimated patient census of 68, yielding an apparent prevalence ratio of about 1/3500, about half as much. If New Zealand and Tasmania are included with the first group, the apparent prevalence in the well serviced areas rises to 1/396, about 9 times as high as the apparent prevalence in the less well serviced areas.

2. *Incidence.* None of the figures are suitable for racial comparisons except those of New Zealand. The writer has previously attempted to demonstrate that hospital admission rates indicate the tendency of various groups to seek hospitalization, rather than reflecting incidence(3). With this in mind, the first admission rates for Europeans and Maoris (Polynesians) in New Zealand can be compared for the years 1953-1956(4). The crude figures per 100,000 are 113.9 and 67.3 respectively. If these figures are adjusted by excluding senile, presenile, and arteriosclerotic psychoses, as suggested by the Medical Statistics Branch of the Department of Health in Wellington, in order to compensate for the relative preponderance of older people in the European population, they are reduced to 85.5 and 60.3 respectively. The first-admission rate of endogenous psychoses (schizophrenia and manic-depressive psychoses) are 37.6 for Europeans and 34.9 for Maoris.

EXPLANATORY NOTES

Dutch New Guinea: There is a mental hospital at Hollandia with 29 patients, and an estimated 16 admissions per year. In 1957 there were 61 psychiatric patients admitted to general hospitals. The estimated psychiatric census would be at least 90, excluding cretinism due to dietary deficiency in the unexplored mountain area (5).

Papua-New Guinea: This territory contains some of the last remaining unexplored and most primitive regions in the South Pacific. There is a mental hospital near Port Moresby with 26 patients(6). The estimated psychiatric census of the area is 600(7). The following is an example of the difficulties and errors which arise in estimating prevalence from hospital statistics.

There were 4 psychiatric patients in the

General Hospital at Rabaul, New Britain (6). One of these was from the village district of Toma. The Assistant District Officer at Toma, however, was able to recall 9 psychotic individuals in his jurisdiction.

British Solomon Islands: There is a mental hospital at Kukum, on Guadalcanal, near Honiara, with 7 male patients, no females. There are about 4 admissions per annum. No psychiatric patients are admitted to general hospitals except in transit to Kukum. No estimate of the psychiatric census is available(8).

New Caledonia: There is no separate psychiatric hospital. Patients are admitted to a general hospital with a special quarter for difficult or dangerous cases. There were 96 patients, with about 40 admissions per year. There are also patients in other general hospitals. Hospitalized patients represent only the most acutely disturbed members of the population(9). The figure used is the most conservative possible. The evidence suggests that the prevalence ratio is at least double that given, probably more than 1/365.

New Hebrides: There is a "rudimentary" mental hospital at Vila, with 4-5 admissions per year. Psychiatric admissions to general hospitals are rare. "Minor psychoses seem much more common in Tanna, where a cargo cult persists, than elsewhere"; but no figures are available(10). The psychiatric aspects of cargo cults remain to be elucidated.

Fiji Islands: The figures include 172 patients in hospital, and 200 on leave as of June 1, 1958(6, 11). I have added an estimated 184 sociopaths to these figures, calculating on ratios derived from a detailed analysis of the 1954 figures which has been published elsewhere(3).

Tonga: There is no mental hospital(6), but an "asylum" near the main jail in Nukualofa with 6 patients, and about 8 admissions per year. About 10 patients per year (principally hysteria and anxiety neuroses) are admitted to general hospitals(12).

Western Samoa: Five-six senile patients are kept confined (1956)(6). The CMO at that time stated that there were other psychiatric patients concealed in the villages. The figures given in the table, however, are derived from information supplied

by the present CMO, who also states that "only those who become troublesome are likely to come to the notice of the health authorities" (13).

American Samoa: There is no mental hospital. There are 3 psychiatric patients in the general hospital, with an admission rate of one or two per year. The census estimate is 5-6 psychotics, "perhaps many more undetected." "In evaluating mental health statistics from less developed areas . . . the figures in general will underestimate the extent of the problem." *E.g.*, those afflicted with mental disease are likely to go to their own bush doctors rather than the white doctors (14).

Cook Islands: There is a 4-bed mental hospital attached, as is common in under-developed areas, to the Tuberculosis Sanatorium, with "never more" than 2 admissions per year. There are no psychiatric patients in general hospitals (15).

French Oceania: There is a mental hospital near the general hospital in Papeete, Tahiti, with 12 patients (6). The estimate given represents psychiatric cases actually diagnosed in 1956, the latest year for which firm figures are available (16). Again, the indications are that the prevalence ratio could safely be doubled. In the opinion of the CMO, the Tahitians are a nervous race, particularly apt to express their emotional difficulties through skin disorders.

New Zealand: The census figures are for 1956, the latest available, and include 9,848 patients in hospital and 880 absent on probation or escape (4).

Tasmania: These well-organized figures include 351 Mental Defectives, 114 of whom are living in the community (17). The population is almost completely Caucasian, the last full-blooded indigene having died in 1876.

There are some island groups lying within the delineated area which have not been mentioned because they have populations of less than 5000 (2). These include the southern Line Islands, the Phoenix Islands, Nauru, Nuie, Norfolk Island, and the Tokelaus. The last are administratively included with Western Samoa.

Thanks are due to all those medical officers who gave me their assistance by supplying information about their areas,

and in many cases offered me their personal hospitality as well.

SUMMARY AND CONCLUSIONS

Figures are offered representing a psychiatric census of the South Pacific.

1. The apparent prevalence is in almost direct proportion to the ratio of practitioners with medical training in each area.

2. The apparent prevalence is related to the availability of special hospital facilities for psychiatric patients.

3. The apparent incidence (first admissions) for endogenous psychoses is approximately the same for Caucasians and Maoris (Polynesians) in New Zealand.

These findings do not contradict, and tend to support, the hypotheses (a) that the reservoir of endogenous psychoses (true prevalence) maintains a constant ratio regardless of racial, cultural, geographical, and socio-economic conditions; and (b) that psychiatric hospital figures are functions of variables other than true prevalence or incidence.

MURDER WITHOUT APPARENT MOTIVE : A STUDY IN PERSONALITY DISORGANIZATION ¹

JOSEPH SATTEN, M.D., KARL MENNINGER, M.D.,
IRWIN ROSEN, Ph.D., AND MARTIN MAYMAN, Ph.D. ²

In attempting to assess the criminal responsibility of murderers, the law tries to divide them (as it does all offenders) into two groups, the "sane" and the "insane." The "sane" murderer is thought of as acting upon rational motives that can be understood, though condemned, and the "insane" one, as being driven by irrational senseless motives. When rational motives are conspicuous (for example, when a man kills for personal gain) or when the irrational motives are accompanied by delusions or hallucinations, (for example, a paranoid patient who kills his fantasied persecutor), the situation presents little problem to the psychiatrist. But murderers who seem rational, coherent, and controlled, and yet whose homicidal acts have a bizarre, apparently senseless quality, pose a difficult problem, if courtroom disagreements and contradictory reports about the same offender are an index(1).

It is our thesis that the psychopathology of such murderers forms at least one specific syndrome which we shall describe. In general, these individuals are predisposed to severe lapses in ego control which makes possible the open expression of primitive violence, born out of previous, and now unconscious, traumatic experiences. The syndrome of periodic breakdown in control and its place in a homeostatic concept of mental illness has previously been described by two of the authors(2). It is the purpose of this paper to illustrate that concept in a clinical study of one type of murder.

The authors examined 4 men convicted of bizarre, apparently senseless murders, as part of an appeal process. All had been examined by psychiatrists prior to their trials, and found to be "without psychosis" and "sane." Three of the 4 were under death sentence, and one of them was serving a long prison term. Further psychiatric in-

vestigation was requested because someone in each of these cases, either the lawyer, a relative, or friend, was dissatisfied with the psychiatric explanations previously given, and asked: "How can a person, as sane as this man seems to be, commit an act as crazy as the one he was convicted of?"

DESCRIPTION OF CASES

A.—Thomas: A 31-year-old chief petty officer in charge of a hospital, while talking casually to the 9-year-old daughter of one of his superior officers, suddenly grabbed the child, choked her, and held her head under water long after she was dead. A discontinuity existed in Thomas' mind as to what happened; he could not remember the beginning of the assault, but "suddenly discovered" himself strangling his young victim.

B.—Adams: A 24-year-old corporal looking for a prostitute near a French town, was approached by a 13-year-old boy who persistently asked him to change Army scrip into French currency; when refused, the boy seemed to mock or make fun of him, whereupon he struck the boy. Adams insisted he had no intention of killing the victim and did not recall the actual killing. When Adams "found out" what he was doing, the victim's body had been severely mutilated.

C.—Mason: A 20-year-old laborer and truck driver, frightened and angry following an argument with a friend, picked up a 14-year-old boy to whom he suggested homosexual relations. The boy refused, and kept "nagging" Mason to take him back home. Mason struck the boy, and began choking him. He said he didn't intend to kill the boy, but "found" the victim was dead.

D.—Elliot: A 43-year-old married Negro soldier lapsed into a dreamlike dissociative state under the taunting and mocking of a prostitute attempting to seduce him and get his money. He struck her with a tire jack, killed her, and then mutilated and dismembered her body.

For the most part, the murderers themselves were puzzled as to why they killed their victims. Attempts to reconstruct a rational motive were unsuccessful. In each

¹ Read at the 115th annual meeting of the American Psychiatric Association, Philadelphia, Pa., Apr. 27-May 1, 1959.

² The Menninger Foundation, Topeka, Kan.

case, there was no gain to the murderer by killing the victim, nor was there any accompanying crime. The victims were relatively unknown to the murderers, and the method of the murder was haphazard and impromptu. In no case did the murderer use a conventional weapon, but killed either with his bare hands or whatever could immediately be pressed into use. In all instances, however, the murder was unnecessarily violent, and sometimes bizarre, and there was evidence that the assaults on the bodies continued until long after the death of the victims.

Our study was primarily "cross sectional." It consisted of a careful exploration of the patient's mental functioning in 10 to 12 hours of clinical interviews and 5 to 6 hours of psychological testing. A history of the patient, as given by himself and others, was used in an attempt to understand the early roots of the behavior disturbance, and its course throughout his life. Physical and neurological examinations, including EEG's, were also done.

HISTORICAL FINDINGS

The most uniform, and perhaps the most significant, historical finding was a long-standing, sometimes lifelong, history of erratic control over aggressive impulses. For example, 3 of the men, throughout their lives, had been frequently involved in fights which were not ordinarily altercations, and which would have become homicidal assaults if not stopped by others. Officers who observed one of these men during several such attacks reported that it required 7 to 10 strong men to restrain him until sedatives took effect, for he was able to break through strap restraints and restraining jackets. This same man had been involved in sadistic attacks on children over a period of many years; on one occasion he nearly drowned a girl in a swimming pool; on another occasion he was thought to have killed a patient while working in a hospital; and he himself gave a history of unnecessarily killing children and civilians while on duty in wartime Europe.

Despite the violence in their lives, all of the men had ego-images of themselves as physically inferior, weak, and inadequate;

and the histories revealed in each a severe degree of sexual inhibition. To all of them, adult women were threatening creatures, and in two cases, there was overt sexual perversion. All of them, too, had been concerned throughout their early years about being considered "sissies," physically undersized, or sickly.

In all 4 cases there was historical evidence of periods of altered states of consciousness, frequently in connection with the outbursts of violence. Two of the men reported severe dissociative trance-like states during which violent and bizarre behavior was seen, while the other two reported less severe, and perhaps less well-organized, amnesic episodes. During moments of actual violence, they often felt separated or isolated from themselves, as if they were watching someone else. One of them, Thomas, in relating the details of the murder said, "I knew that I was doing it, but somehow it didn't seem like me. It was as if I was watching myself do it." This feeling that it was not he who committed the murder enabled him to successfully pass a "lie detector" test, at the conclusion of which, however, he impulsively confessed.

Also seen in the historical background of all the cases was the occurrence of extreme parental violence during childhood, a finding which has also been reported in studies of murderers by Duncan, *et al.*(2). One man said he was "whipped every time I turned around." The theme of open violence dominated his early experiences. His earliest memory of himself was of almost being killed in a cotton gin; his earliest memories of his father were of him coming home beaten up, bloody, and with broken ribs. Severe corporal punishment was something he took for granted as one of the natural phenomena of life. Another of the men had many violent beatings in order to "break" him of his stammering and "fits," as well as to correct him for his allegedly "bad" behavior.

In some of these cases, the violence was associated with the sexual behavior of grown-ups. One man, Elliot, from his early life onward was an observer of much drunkenness, fighting, and promiscuity among his parental figures, and he was frequently drawn into their physical vio-

lence. Another reported that, as a child, he was frequently kept awake by the drunken fighting accompanying the sexual activity of a couple next door, whom he could observe or hear through the common wall separating their bedroom from his. Although our examination stopped considerably short of the intensive exploration of the unconscious necessary to fully confirm psychoanalytic hypotheses, our data permit the inference that the murderers probably fantasied or actually observed the primal scene as something overwhelmingly violent and sadistic.

The history relating to *extreme* violence, whether fantasied, observed in reality, or actually experienced by the child, fits in with the psychoanalytic hypothesis that the child's exposure to overwhelming stimuli, before he can master them, is closely linked to early defects in ego formation and later severe disturbances in impulse control.

In all of these cases, there was evidence of severe emotional deprivation in early life. This deprivation may have involved prolonged or recurrent absence of one or both parents; a chaotic family life in which the parents were unknown; or an outright rejection of the child by one or both parents with the child being raised by others. Although the depth of the examinational data varied, in some cases it was possible to demonstrate links to early and severe oral deprivation. For example, Mason had been a colicky, crying baby who was suddenly weaned in two days at the age of one year but remained a feeding problem for several years thereafter, during which time he ate dirt, gravel, and sand and acted as if he was constantly craving food.

Three of the men had a definite history of stuttering in childhood, and under stress, traces of this could be seen in their adult functioning. The fourth one, though without a history of speech disturbances, frequently found himself inarticulate and groping helplessly for verbal expression. This finding confirms that of Greenacre (4), who correlates early speech difficulties with the ego's failure to develop adequate mechanisms for delaying impulse discharge, or for diverting impulses into ideational and verbal, rather than motor outlets.

EXAMINATIONAL DATA

In addition to the similarity in historical findings described above, a number of common characteristics emerged in the clinical examinations. The data cited below illustrate the total functioning of these men and no single item in itself should be taken as a diagnostic sign of the personality disorder we are describing.

The most striking similarity in the examinational findings was in disturbances of impulse control. During the examination, a pattern of erratic impulsivity was observed: their speech could quickly shift from a blocked, groping, at times almost aphasic inarticulateness to an explosive gushing of words; their bodies would grow stiff with tension as they sought to contain the rising charge of affect and anxiety that would sporadically well up within them. They tended to show either extreme over-control and inhibition, or marked restlessness and hyperkinesis (pacing the room during the testing and clinical interviews was not an uncommon occurrence).

Evidence of this brittle quality of impulse control was seen clearly in the psychological tests. In general, the test picture for all of the men added up to an "all or none" pattern of functioning. Inhibition of action required great amounts of psychic energy and lacked flexibility; once controls began to weaken, the men were almost completely overwhelmed by affect, morbid fantasy, and a proneness to immediate unreflective action. The test pictures were uniformly consistent with indications of a severe ego deficiency which permits impulse to flow too directly into action and not be easily shunted into thinking or verbalization. Details of test responses are described in another paper (11).

Manifestations of a bizarre, violent, and primitive fantasy life were seen in each of the men we examined. Repetitive dreams of violently killing, mutilating, burning, or destroying others were seen; the brief TAT stories of these men were filled with a quality of primitive, murderous hostility, in some cases glibly rationalized on the basis of the victims having "provoked" their murderers, and in others precipitated by rejection or rebuff, usually implying oral deprivation. Although the hostility and de-

struction pervading their fantasy lives were easily observed, conscious fantasy or ideational activity was minimal. Brief constricted Rorschach records and meager, frequently autobiographical, TAT stories were the rule. Certainly the usual role of thinking (as a delay of, and attenuated substitute for, action) was conspicuously absent in these cases.

There was a blurring of the boundaries between fantasy and reality, and there were transient feelings of depersonalization. In one extreme example, Elliot, what really occurred, or what the man thought, or dreamed, were all blurred in a hazy, nebulous series of memories, and it was extremely difficult to construct a verifiable sequence of what actually happened. In response to a Rorschach card, for example, he began to describe not only the blot in front of him but a confused mixture of dreams, memories, and waking fantasies. Two of the men described episodes in which they thought they might have killed people, sometimes later returning to the scene of the "killing" to find a dead body, but they remained still unsure as to whether the episode was real, a dream, or a fantasy.

Evidence of disturbances in affect organization was seen. Most typically the men displayed a tendency not to experience anger or rage in association with violent aggressive action. None reported feelings of rage in connection with the murders, nor did they experience anger in any strong or pronounced way, although each of them was capable of acts of enormous and brutal aggression. The tolerance for affect and anxiety in these individuals was also extremely limited. All showed marked disturbance in dealing with color on the Rorschach test and their TAT stories showed a preponderance of violence, most typically without accompanying affect. As formulated by Rapaport, affect is conceived of as an impulse derivative, generated through the ego mechanisms of delay and control (10). For the murderers, these mechanisms were too brittle to produce the methods for "darning up" and appropriately discharging impulses that are necessary for a graduated and variegated affective experience.

Their relationships with others were of a shallow, cold nature, lending a quality of

loneliness and isolation to these men. People were scarcely real to them, in the sense of being warmly or positively (or even angrily) felt about. In their early memories and psychological test material appears the re-institution of an idealized, all-giving mother figure, but always in the context of loss or rejection, leaving the world, for these men, bleak and empty.

The 3 men under sentence of death had shallow emotions regarding their own fate and that of their victims. Guilt, depression, and remorse were strikingly absent.

The most questionable examinational finding involved the evidence relating to organic brain damage. Two of the men showed neither historical evidence, neurological nor EEG findings that would in any way be consistent with organic brain pathology—nor were there any such indications on the psychological tests. The other two men in our sample revealed ambiguous findings. One reported a history of childhood convulsions, and his associational blocking, severe constriction, and aphasic-like speech difficulty raised the question of the possibility of organic brain pathology. The psychogenic meaning of these symptoms was clearly demonstrated in some hypnotherapeutic sessions (3), and in the face of negative neurological studies, organic damage seemed ruled out. The organic findings on the other man were the most definite of our sample (previous EEG studies were "suggestive" of organic brain damage), and his history revealed a severe head injury at age 10 followed by personality disturbances of even greater severity than those noted prior to the accident.

The negative evidence, however, was not absolute, for we used only regular and sleep EEG's in search for evidence of a convulsive disorder. We did not use EEG activation techniques, such as metrazol, photic stimulation, etc. It would not be surprising, however, in view of the equivocal evidence with routine methods, to find evidence of some organic or physiological factors with more refined methods of neurophysiologic investigation (5, 7, 12).

THE ROLE OF UNCONSCIOUS MOTIVATION

The individuals described above can be considered to be murder-prone in the sense

of either carrying a surcharge of aggressive energy or having an unstable ego defense system that periodically allows the naked and archaic expression of such energy. The murderous potential can become activated, especially if some disequilibrium is already present, when the victim-to-be is unconsciously perceived as a key figure in some past traumatic configuration. The behavior, or even the mere presence, of this figure adds a stress to the unstable balance of forces that results in a sudden extreme discharge of violence, similar to the explosion that takes place when a percussion cap ignites a charge of dynamite.

One man, Mason, had such varying targets of aggression that it was impossible to delineate precisely their meaning in his unconscious conflicts from the data obtained. For Elliot, whose case included a series of hypnotherapeutic interviews, his victim seemed to have multiple unconscious meanings, although the predominant one related to his deceased girl friend, toward whom his feelings were intense but ambivalent. In Thomas, sodium amytal interviews yielded material suggesting that the victim mainly represented a dead sister, with whom he had had a conflictual, incestuous relationship. For Adams, the murder appeared to have been a deflected suicide, as impulsive murders have occasionally been interpreted (8, 9, 13). The victim represented by the murderer's own hated self-image; the young boy he killed was a camp pet who ran errands for the soldiers, just as he himself had been a mascot for the men in his father's lumber camp.

The hypothesis of unconscious motivation explains why the murderers perceived innocuous and relatively unknown victims as provocative and thereby suitable targets for aggression. But, why murder? Most people, fortunately, do not respond with murderous outbursts even under extreme provocation. The cases described, on the other hand, were predisposed to gross lapses in reality contact and extreme weakness in impulse control during periods of heightened tension and disorganization. At such times, a chance acquaintance or even a stranger was easily able to lose his "real" meaning and assume an identity in the unconscious traumatic configuration. The "old"

conflict was re-activated and aggression swiftly mounted to murderous proportions.

Such outwardly senseless attacks on relatively unknown persons are different from those arising out of protracted but conflict dominated relationships, such as with a wife, child, or parent, *e.g.* catathymic crises (13). The question of the factors involved in the "choice" of the "unknown" victim in these cases goes beyond the scope of this paper. Research now in process suggests a range of selection factors whereby, for some impulsive murderers, almost any other human being can activate the tremendous destructive potential, while for others, only a highly specific person or action is required.

A finding significant for social administration is the fact that 3 of these 4 murderers had conveyed their fears of losing control to legal officials or psychiatrists *before the murders took place*. The warnings were disregarded.

SUMMARY

In this paper we have described a number of common characteristics found in individuals who have committed impulsive senseless murders. These characteristics were: severe weakness of impulse control; blurring of the boundaries between fantasy and reality, with periods of altered states of consciousness; blunted and shallow emotional reactions; and a violent and primitive fantasy life.

This constellation seems to have grown out of a history characterized by extreme parental violence and early severe emotional deprivation. In these cases, there appeared an ego weakness which allowed the periodic breakthrough of intense aggressive impulses, sometimes of homicidal proportion.

When such apparently senseless murders occur, they are seen to be an end result of a period of increasing tension and disorganization in the murderer starting before the contact with the victim who, by fitting into the unconscious conflicts of the murderer, unwittingly serves to set into motion his homicidal potential.

It remains a task of future research to:

1. Differentiate these individuals from other murderers as well as from others with

similar disturbances but who do not kill ; 2. Weigh the significance of the individual factors described ; 3. Devise measures for identifying and effectively controlling these individuals before they commit murder.

THE HYPOTHESIS OF RECIPROCAL COMPLEMENTARITY

A. H. HOBBS, PH.D.¹

THE PROPOSITION

The hypothesis of reciprocal complementarity postulates that moral codes are as truly an integral factor in the functioning of adult civilized human beings as are the internal emotional drives; that such codes, as incorporated into the social controls, constitute a complementary element in man's emotional functioning rather than being arbitrary conventionalities which are antagonistic to it. It is a technique to demonstrate that in the relationship between his internal selfish drives and the codes of civilized conduct, man has the capacity to discriminate; to select or reject; and that he is, in consequence, a positive element in this relationship between emotional urges and social controls, and a responsible agent in the self-society matrix.

THE PREMISES

Normal Man in Civilized Society. The subject of analysis is normally intelligent man in civilized society; not idiots, not cats in boxes nor rats in mazes, not short-lived and atypical primitive groups nor the so-called wolf-children or antelope-boys supposedly raised by animals.

Codes an Integral Part of Life. That man, by his nature, cannot normally survive alone; that life in some form of society is an intrinsic factor in human functioning; and that the social codes necessary to make such a life possible are as real an element in his relationships as is water to the functioning of a fish or air to the flight of a bird.

Codes are Reciprocal and Complementary to Self. That, in principle, such codes are, in the overall pattern of civilized living, reciprocal and complementary to his self-drives rather than antagonistic to them. If one is endowed, for example, with a high degree of physical strength and quick reactions, he will find greater fulfillment in channeling his abilities through the con-

trols regulating such activities (rules for boxing, football, baseball) than he would through using his prowess to clobber old ladies.

Individual Differences. That differences in age, sex, physical and mental capacities, and endocrine functioning exist to differentiate people in their relationship to the external social and physical environments. That the aspect of this social environment which is customarily designated "The Culture" is not a unified monolith which stamps everyone into the same mold, but that individual reactions to the impress of culture are selective in terms of individual differences and in terms of the degree of awareness of the end-product to be attained. Even in relation to elements of the culture which apply to all, such as language, our response is selective in terms of what Koffka (1935) designates the "Behavioral Environment"; differentiating the child from the adult, the man from the woman, the tone-deaf and the color blind, the starving and the satiated.

Circular Causality. That human relationships characteristically involve circular causality rather than straight-line cause-and-effect. This circular causality can be either initiated, facilitated, or inhibited by any one of the several elements involved; these being muscular reactions, glandular or other chemical influences, mental coordination and mental imagery, and external stimuli, including moral codes.

Since the higher levels of the brain have the capacity to fit reactions into a pattern which is meaningful in terms of the external environment as well as in terms of the internal (bodily) environment, their functioning in the form of conscious thought is one of the elements which can initiate, facilitate, or inhibit human reactions. With this capacity, the individual is an active determining agent in his responses rather than a puppet at the mercy of unconscious drives or of unthinking indoctrination through cultural conditioning. As brain (mind) and muscles and glands (matter) are functionally interrelated, so too is the brain and the moral

¹ Assoc. Professor of Sociology, University of Pennsylvania, Philadelphia, Pa.

substance of the environment, the social controls.

External Homeostasis. That in a fashion similar to the process by which the various parts of the brain coordinate muscular and glandular internal reactions to keep them in balance which is called *homeostasis*, so the higher levels of the brain strive to coordinate, to make meaningful patterns of the moral codes and ethical principles which constitute the social controls. *That homeostasis exists in relation to the external social environment as well as in relation to the internal milieu of the body.*

Incomplete and Unbalanced Homeostasis. That the higher levels of the brain have the capacity to coordinate internal drives and external social imperatives into patterns which are meaningful in terms of both, fusing the internal homeostasis with the external into intellectually satisfying, emotionally gratifying, socially responsible behavior. Yet the very complexity of these higher mental levels also endows human beings with the capacity to form patterns which are meaningful to the internal tensions of muscles and glands but inconsistent with the social controls, and *vice versa*. Or, the patterns may be crazily inconsistent with both internal and external conditions. Illustrative of the first unbalanced situation would be the rationalization of unchained lust or unbridled brutishness. A situation wherein external homeostasis is attained at the expense of internal homeostasis would occur where the realities of the internal drives would be smothered by arbitrary conventions which deny their existence. Imbalance of both occurs in mental disorder, alcoholism, drug addiction and other socially defined aberrations.

Antagonisms become Complementary. That elements of reaction which are separately antagonistic combine in reciprocal and complementary relationships to form new functional syndromes.

THE ARGUMENT

The codes and precepts which constitute the social controls are made up in large measure of "Don't's" and "Thou, Shalt Not's" which appear to be antagonistic to individual desires. This impression that the social controls are antagonistic to the "nat-

ural" self-drives leads some persons to think of them as dogmatic, unrealistic, arbitrary conventions made up by old men who hate to see anyone have any fun.

To demonstrate that the social controls are (or can be) reciprocal and complementary to the individual desires rather than antagonistic to them, it is necessary to show that reactions on all levels (muscular, glandular, and mental) characteristically if not invariably involve a combination of units which are separately antagonistic but which function reciprocally to form new functional units—the functional unit in this case being human relationships in civilized society.

Though my concern is with the relationship between the person and his codes of civilized living, if this hypothesis is valid it should apply to all levels of reaction. It should explain the functioning of muscles, glands, and the brain, separately and in conjunction with each other, as well as describe the relationship between individuals and the moral codes of society.

Illustrations of the process will be drawn, therefore, from each of these types of reaction before indicating how it relates to the person and the social controls.

Muscular Functioning. In breathing, the contraction of the muscles of the thoracic diaphragm which occurs when we inhale is accompanied by a relaxation of the abdominal muscles which, conversely, tense when the diaphragm relaxes during exhalation. Such contraction of the abdominal muscles could be looked upon as being antagonistic to the relaxation of the thoracic diaphragm, but in the syndrome of breathing the two sets of muscles form a reciprocal and complementary functional unit.

Environmental factors such as atmospheric pressure and the oxygen content of the air are also vital factors in the process. Individual differences exist in the form of age, sex, the size of the thoracic cavity, strength of the intercostal muscles, shoulder muscles, neck muscles and abdominal muscles, diameter of nostrils, length of passageway, etc.

The rhythm of breathing varies in terms of exercise and rest, waking and sleeping, emotional and sexual reactions. It is not a matter of one set of muscles in these reactions being "good" and another set "bad," or

of feeling that the atmospheric pressure is a bad thing because the intercostal muscles must "work against it" in order for us to live. Without atmospheric pressure we would not exist. Nor is it a matter of inhaling being good and exhaling bad, sleep good, waking bad; exercise good, rest bad, or of these being antagonistic to each other.

Such different rhythms can best be understood through the manner in which they complement each other.

In relation to cause and effect, we cannot legitimately say that the atmospheric pressure causes breathing, because without the functioning of the muscles it would not occur. Nor can we say that the intercostal muscles cause it because they could not produce the phenomenon without the atmospheric pressure, the abdominal muscles, *etc.* Nor is the syndrome produced solely by a combination of muscles. The muscles must function reciprocally and rhythmically (rhythm, according to the hypothesis of reciprocal complementarity, is an integral factor in most reactions) and be coordinated by the central nervous system.

Causation, therefore, is circular, and the rhythm of the pattern can be initiated, facilitated, or inhibited by muscles, glands, brain, or external factors. Thus the doctor whacks the baby's butt to start the cycle, artificial respiration can restore it when stopped, perfume changes the rhythm by expanding the nostrils, stench contracts them to change the rhythm, alcoholic consumption speeds it up, then slows it, finally can stop it if enough is consumed; and a changed rhythm is an integral element in emotional and sexual reactions.

Glandular Functioning. As the muscles which separately function antagonistically combine to function reciprocally and complementarily in most bodily reactions so, too, with the glands. Again, the process is not one of simple straight-line-cause-effect, but a circular one which can be initiated, facilitated or inhibited at any one of a number of levels, involving processes of reciprocity and feed-back such as Harrison(2) describes:

By combination two or more endocrine glands can produce rhythmical or cyclical changes in the prevailing hormonal concentration, the type of hormone acting at the

target area and in response to the target organ. Thus, suppose an endocrine organ B to be under the control of endocrine organ A through mediation of hormone H-1, and that B is caused to secrete a second hormone H-2. Organ B will continue to produce H-2 as long as it is stimulated by H-1 from organ A. But let it be that a certain concentration of H-2 can influence organ A and inhibit production of H-1, and thus lead to a fall in production of H-2. Thus the mechanism reaches a certain level of activity and then cuts itself off, rather like a thermostat controlling a heater. As soon as the concentration of H-2 falls below the cut-out threshold, organ A produces hormone H-1 again, and the process is repeated.

Even, when restricted to the glandular level, most reactions are probably much more complicated than this simple illustration would indicate. For example, recent findings reveal that a drug designated JB-516 is effective as a tranquilizer, lowering blood pressure and decreasing nervous tension. Apparently the favorable effects of JB-516 are due to its inhibiting action upon the enzyme MAO (monamine oxidase). MAO functions to inhibit the accumulation of enzymes such as serotonin, which seems necessary to normal mental and bodily functioning. That is, a given level of serotonin is apparently essential for normal brain functioning, and when the level rises above the limits of tolerance the body produces MAO to inhibit the further accumulation of serotonin. Hypothetically, some persons may produce MAO in such quantities that the proper level of serotonin cannot be attained. With others, an excess of serotonin may be produced in response to either real or imagined stress. Greater quantities of MAO are then produced to compensate for the accumulation of serotonin. A continuation of real or imaginary stress could cause the organs producing serotonin to become exhausted and fail to respond to further distress signals. Meantime, MAO continues to be produced at a high level, thus inhibiting the serotonin to a degree that it falls below the needed levels. To return balance to the relationship, injections of JB-516 inhibit the MAO sufficiently to permit the serotonin component to build up again.

Such reactions (if correctly interpreted in principle, though the details may be in-

correct) would support the principle of reciprocal complementarity, but it is not thereby assumed that this is a simple cause-effect interpretation. Even with such a simple-seeming thing as the discovery of a new insecticide which functions by inhibiting the growth hormones of insects it was found that : 1. The growth hormone was secreted in the brain ; 2. But equal evidence showed that the brain hormone triggers growth glands in the prothorax ; but 3. The secretions from both sets of glands were governed by another hormone which postpones maturation until the insect has reached the proper size.

These functional connections do not simply involve *a hormone or a gland doing this or that*, but a relationship between a series of glands in terms of timing and rhythm, with this timing and rhythm being influenced by other conditions of the body and brain and by environmental factors such as food and temperature.

With humans, where the brain plays a much more vital role in coordinating the timing and rhythm (or in interfering with it), the situation, while analogous, is infinitely more complex. In man, it is generally held that the pituitary gland (hypophysis), located in the brain-case, is the master coordinating gland, yet the pituitary itself is influenced by the hypothalamic centers of the brain which, in turn, are under the influence of the cerebral cortex, and consequently the circular causal nexus involves also the external environment and mental imagery.

Mental Functioning. One reaction to such knowledge about glandular and muscular functioning might be : "What's the difference how glands or muscles interact ? The important thing is the mind. Thinking is one thing and the reaction of muscles and glands is something else." This contention is the old issue of mind over matter, psyche versus soma, spirit versus substance. The relevance here is not to contend, as some have, that the glands determine behavior, nor that undefined instincts determine behavior. Nor is it to hold, as did J. B. Watson, that thinking is merely the movement of muscles in the form of silent speech. At another extreme, the psychoanalytic notion

that some mythical "unconscious mind" controls behavior is also rejected.

Here the contention is that mind and body are interrelated and that mind is not only interrelated (affecting and being affected by) with muscles and glands but also with the social as well as the physical external environment (affecting the interpretation of it as well as being affected by it). All are thought of in terms of relationships, not as separate and discrete substances nor as ultimate causes.

When we use the term "mind" we are likely to think of it in terms of abstract thought. But such thoughts, no matter how abstract, are produced through functioning interrelationships between physical substances—the neurons of the brain. If we tend to think of mind *versus*, or separate in its functioning from the body, we must reconcile this belief with the fact that the brain contains coordinating centers for glands and muscles as well as for sight, hearing, smell and touch.

Yet, it is an oversimplification to say that mind is merely the functioning of matter or that the human brain is merely an enlarged insect-ganglion or a highly developed ape-brain. The position taken here is that the human brain is characterized by a unique difference in being capable of real abstraction and of coordinating ideas such as those embodied in the social controls as well as by the ability to coordinate internal and external physical stimuli. That the human brain is qualitatively as well as quantitatively different from that of even the highest of the infra-human animals :

A comparative study of structural and functional differentiation in the cerebral cortex throughout the mammalian series, including man, shows clearly that as the cortex increases in expanse it also undergoes regional differentiation in consequence of which more and more cortical areas can be mapped out on the basis of structural differences. These structural differences are not without functional significance ; consequently *new cortical areas may in a very real sense be regarded as new cortical organs*. Many of the cortical areas mapped out in the human cortex have no counterpart in any of the lower mammals. The human cortex, therefore, should not be regarded merely as a quantitative multiplication of the animal cortex, but it possesses

functional capacities, particularly in the psychic realm, which are not represented in any of the lower mammals(4). (My italics.)

Similarly, the late K. M. Bykov(1) summarized the numerous controlled studies of conditioning contained in *The Cerebral Cortex and the Internal Organs* by stressing that with man (and in most cases with other higher vertebrates as well) conditioning is not a reflexive reaction but a cortical reaction :

The cerebral cortex keeps adapting this inner world to the conditions of its environment at every given moment. Thus, the cerebral cortex does not only reflect the outer world but also the inner world of the animal. This reflection, however, should by no means be regarded as a passive process. It ensures the active functioning of the organs of the organism as a whole, which functioning not only maintains the organism in a state of equilibrium with its environment, but also changes this environment.

The starting and regulating cortical mechanisms are the most sensitive adjusters of the responding apparatus not only by changing their activities both qualitatively and quantitatively, but also by changing their time relations. *Stimuli conveyed from the cerebral cortex have a striking capacity for changing the rate of reaction, for establishing the sequence of events, and, if necessary, for inhibiting the course of any process.* (My italics.)

If the cerebral cortex can change the rate of reaction, establish the sequence of events and inhibit the process of conditioning, it probably does so as a function of the degree to which the new reaction fits into (or conflicts with) already established cortical patterns, i.e., on the basis of the (rationality) of the conditional response to the individual.

The next step in reasoning, which to me seems inescapable, but which the Russian investigators fail to acknowledge, is to recognize that the cortex also assimilates and coordinates moral codes as well as other elements of the external environment and that all of these must then be assimilated into a pattern which constitutes the unique-

ness of the individual; the basis for his integrity as a person. Contrary to Marxist dogma of cultural conditioning, man is an active agent in his response to social situations, affecting them as well as being influenced by them, reacting selectively, not as a puppet.

SUMMARY

If human functioning on the muscular, glandular, and mental levels characteristically involves circular causality rather than direct cause-effect and if, further, elements which separately function antagonistically combine reciprocally to complement each other in new functional nexuses, it seems reasonable to infer that a similar situation of circular causality and reciprocal complementarity exists between the individual and his moral codes. Since he has the power to assimilate concepts of morality in the cerebral cortex, and since the cortex is one of the factors which can initiate, facilitate, or inhibit his response, man is a positive and responsible agent rather than a passive puppet in the self-society nexus.

In a subsequent article I shall show how mental disorder, alcoholism, and other conditions (and their therapy) can be interpreted in terms of reciprocal complementarity. I hope to demonstrate that at least some of the seeming contradictions in such conditions which cannot be explained by conventional cause and effect nor in terms of antagonism between emotional drives and the social controls can be explained in terms of circular causality and complementarity between man and the social codes through which he functions.

SOME PATHOLOGICAL FINDINGS IN SCHIZOPHRENICS

DONALD L. HOWIE, M.D.¹

Nobody knows what causes schizophrenic symptoms. In the present state of our knowledge, we can only cling to suggestions as points of departure for further investigations. The following experiences with the anatomical pathology of schizophrenics tend to reaffirm some older suggestions of pathogenesis and suggest further items for investigational attention. In addition, the material indicates a position on the syndrome-disease contention regarding schizophrenia.

MATERIAL

Fifty consecutive autopsied patients were chosen solely on the basis that they had been diagnosed as schizophrenic. Many factors were charted including items of history, standard individual data, and physical and pathological findings.

Patients were recorded as hypertensive only when pressures over 160/90 mm. Hg were noted. In most cases, more than one elevated pressure had been recorded and several had systolic pressures over 200 mm. Hg. Rheumatic heart disease was diagnosed on the presence of mitral valvular fibrosis with varying degrees of stenosis. Some of these had recent vegetations and myocardial inflammation and fibrosis, but none had typical Aschoff nodules. A few had aortic valve deformities also, but none had significant pulmonary or tricuspid valve damage. Basophilic change in the cerebral arteries was recorded when the medium sized and smaller arteries were infiltrated and surrounded by fine to coarse basophilic granules of ground glass to laminated appearance. These usually were found in the basal ganglia, dentate nuclei or both. Diagnoses of arteriosclerotic disease were based on the presence of definite arterial change plus evidence of related tissue damage. Malformations were recorded when there were decided alterations in the convolutional pattern, hypoplasias, anomalies of the circle of Willis,

or decided deformities of the calvarium. Hemangiomas were also recorded as anomalies since there were no characteristics of neoplasia. For comparison, the incidence of some of these processes was determined in 200 other randomly selected autopsies done by the same person in the same hospital during the same time period.

HYPERTENSION

Distinctly elevated blood pressures were present in 17(34%) of the schizophrenics. As might be expected, the average age of death in this group was 75 years as opposed to an average age of death of 64 years in the remaining 33 patients. As might not be expected, however, the average age of onset of psychosis was 43 years in the hypertensives as opposed to an average onset age of 34 years for those without hypertension.

It should be noted that only rarely was hypertension present on admission. The usual pattern was the development of hypertension after some time in the hospital with, frequently, a return to normotensive levels during a protracted terminal phase with cachexia. At autopsy, some had hearts within normal weight limits, even although older X-rays had shown cardiomegally. As with any group of hypertensives, considerable coronary, renal and general arteriosclerosis was present.

Brain findings were not always characteristic, but generally in severe hypertension there was hyaline thickening of the smaller cortical vessels. Conversely, when this was present, hypertension generally coincided. Less specific findings included perivascular spacing, larger artery cellular and hyaline thickening, perivascular accumulation of brown pigmented macrophages and lymphocytoid cells, minor to major areas of encephalomalacia, and some irregular gliosis, neurone loss and interstitial accumulation of crystalline brownish pigment. These changes were generally most marked in the basal ganglia and dentate nuclei. In only one case did recent major hemorrhage occur. In about one-half of the

¹ Former Director of Clinical Laboratories, Fairfield State Hospital, Newtown, Conn. Present address, Milford Memorial Hospital, Milford, Dela.

patients cardiac murmurs had been noted. Basophilic vascular changes occurred in some cases but by no means exclusively in this group. Two of the 4 cases of subacute bacterial endocarditis occurred in patients in whom hypertension was the major cardiovascular disease. In 2 patients recent myocardial infarcts were the proximate cause of death.

RHEUMATIC HEART DISEASE

This was present in 7 (14%) patients. Only 2 of these had a good history of rheumatic fever and one had a history suggestive of chorea. Two of the 7 rheumatics also had subacute bacterial endocarditis. Of the remaining 43 patients, one had a history of rheumatic fever and another had a history of childhood chorea. Both showed cerebral arterial changes as described below but neither presented anatomical evidence of cardiac damage. The control group contained 15 rheumatics (7.5%).

The most characteristic change in the cerebral vessels in the rheumatic group consisted of irregular cellular thickening and reticular splintering of the fine vessels of the cortex. About some of the more ragged vessels there was neurone loss and irregular gliosis. Of course, in the SBE cases there were inflammatory cell infiltrates and larger focal areas of destruction. However, even in those without SBE, focal cortical lesions of intermediary character were seen. While these changes were common, the fact that similar changes occurred in individuals not thought to be rheumatic indicates their nonspecific nature.

In order to test the degree of specificity, random slides of cortex were examined and classified as rheumatic brains or not. Two of 4 patients with rheumatic heart disease were correctly classified while 8 of 50 without rheumatic heart disease were incorrectly classified. This is hardly spectacular, and agrees with Costero's(1) finding that the adult rheumatic does not have pathognomonic findings in the brain.

MALFORMATIONS

More than minor alteration in the brain or calvarium occurred in 12 (24%) patients in the schizophrenic series as opposed to 17 (8.5%) in the nonschizophrenic group.

Anomalies of the circle of Willis are not included in these figures, but did occur in 10 patients. This is considered usual for unselected psychiatric patients(2), but is lower than the incidence found in the arteriosclerotic psychiatric patients.

Anomalies noted were two hypoplasias of the cerebrum, one cerebral cyst, one microgyria, one microgyria with fore-shortened frontal lobes, one peculiar hooking of the occipital pole due to deviation and anomalous insertion of the posterior part of the falx, one short frontal lobes with unusual increase in the periventricular ependyma, one true platybasia, one hemangioma, one foramen magnum deformity not constituting a true platybasia, one shortened flattened posterior fossa again not a true platybasia, and one alteration in the temporal lobe pattern almost resembling that seen in the mongolian brain. None of the 3 patients noted to have mental deficiencies was in this group of anomalies. However, some of the historical events in a few of these cases raised questions of the level of their intellectual abilities.

MISCELLANEOUS FINDINGS

Senile plaquing was seen only occasionally, and the only marked involvement was in a patient with rheumatic heart disease and subacute bacterial endocarditis. Histories of rather marked alcohol intake were noted in 7 patients, but there was no particular correlation with any of the other factors. Extracranial malignancies were noted in 7 patients. Traumatic brain damage was present in 4. Positive VDRL's were present in 3 patients, but there was neither clinical nor pathological evidence of central nervous system syphilis. Three patients had mental deficiency of long standing and one of these was a patient with rheumatic heart disease.

Basophilic arterial change was found in 9 (18%) of the schizophrenics and in 15% of the control group. No significant correlations were found with other mentioned factors, but it was noted that 25% of all our patients with this change had cataracts and seldom were diabetic. The youngest of these patients, who died at age 36, had a history of childhood bone infections, intermittent adult neurological findings, and

progressive personality disintegration. *Geotrichum* was isolated from his urine twice about 4 months before his death from sepsis. Multiple small foci of encephalomalacia were present at autopsy and these contained PAS staining bodies resembling one phase of the *Geotrichum* found in the pneumonia. But since brain cultures were not done, identification is quite indefinite. This organism has not been seen as a contaminant or isolated from other patients in this laboratory. It seems the patient must have harbored this organism at least 4 months and perhaps quite a bit longer. This case is of particular interest in view of Papez's(3) material on culturing vascular particles.

Twenty-three patients had evidences of arteriosclerotic brain damage and 10 of these were also recorded as hypertensive. In one patient there had been a distinct change in her behaviour 2 years before death with increasing memory defect and disorientation. This change coincided with discovery of hypertension and fundal and peripheral signs of arteriosclerosis. In most of these patients, however, there was no such distinct clinical change, and their previous modes of behaviour continued with only the more usual signs of deterioration marking progression of their disease.

One patient initially designated as schizophrenic later proved to have progressive muscular atrophy both clinically and pathologically. However, the same mental picture continued throughout the illness. The one patient who died of a ruptured saccular aneurysm of the anterior cerebral artery also had Paget's disease of the skull. There was evidence of previous old bleeding from the aneurysm. She was always dull and silly. Whether this old episode dates back 40 years to the time of her admission is, of course, unknown.

Another patient with a 40-year history had old deformities of the skull and thoracic cage, presumably rachitic. In addition there was a small parasagittal meningioma and an old subdural membrane with old cortical contusion foci. It seemed likely the meningioma was not present at the onset of the psychosis, the deformity was, and the traumatic damage was of uncertain vintage.

Only two patients had no significant

change in the brain. Both were males, both had repeated episodes of alcoholism and both had hepatic changes. The 38-year-old had a fatty liver and surprisingly small adrenal cortices. He died of aspiration with only a 2-month psychiatric illness. The 46-year-old had a 21 year history of psychosis but had been out of the hospital frequently, only to return after another bout of alcoholism. He had a cholangiolitis. He also had an anomalous circle of Willis and died of aspiration after head trauma.

DISCUSSION

Two facts are apparent from this material: 1. Findings are present and 2. The findings are diverse. With full recognition that the presence of findings does not indicate casual relationship, we must still consider these as suggestions of possible cause.

In this series, the incidence of rheumatic heart disease as a possible indicator of rheumatic brain disease is about double in the schizophrenics as opposed to the non-schizophrenics. Most people grant that rheumatic heart disease is directly associated with psychosis in some few cases and that chorea is a result of rheumatic fever in some children. It should be noted that the damage is mainly an arteritis as in syphilis and that embolic damage is secondary in importance. This incidence, plus the factors of known relationships and anatomical findings, makes it likely that rheumatic cerebral arteritis is a real factor in the production of schizophrenic symptoms in some patients.

This is not a simple academic contention. If this is true, then appropriate antibiotic or chemotherapeutic prophylactic and treatment programs might lower the incidence of such disease and perhaps prevent relapses. The results of such a program might shed more light on the truth of the contention. Analyses of current rheumatic fever prophylaxis programs as to later incidence of psychosis in those who did and did not follow the regimen might provide further information.

Hypertensive disease is not generally considered related to schizophrenia. This series at least indicates that hypertension is not rare in these patients. The difference in average age of onset of psychosis in those with and without hypertension would seem

to indicate that these are indeed two different groups. It can be hypothesized that a common antecedent was present which led to the development of both psychosis and hypertension. However, the curves in the two age groups overlap considerably so further information awaits greater experience. The incidence of malformations in this group was almost 3 times that in the non-schizophrenics. On this statistical basis malformations must be considered in enumerating possible causal factors. There is no information as to the incidence of malformations in relatives of these patients, but correlation of such findings might shed more light on possible genetic factors in the pathogenesis of schizophrenia. As indicated, the incidence of basophilic arterial change was not greatly different in the control and schizophrenic groups. But the high frequency of cataracts noted in these patients might indicate a general disease state such as some alteration in epinephrine metabolism.

Some of the individual cases cited suggest that the pathological findings are related to the schizophrenic symptoms. These include the rachitic patient, the lady with the old and recent rupture of the saccular aneurysm, the woman with the progressive muscular atrophy, and the man with the old bone and recent generalized infections with the encephalomalacia and the Geotrichum.

CONCLUSIONS

The diverse findings in this group of schizophrenics tend to support the idea that schizophrenia is, indeed, a syndrome. If this is really so, then attempts to pick groups of patients for clinical research projects

must involve unrecognized heterogeneity, since most of these conditions were unrecognized in life. Research based on such an initial error might be invalid.

The most frequent findings in this group of patients are abnormalities in vessels and grosser features of architecture. This may indicate that too much attention has been paid to neurones and glia. No "black box" works even with intact components unless it is plugged in. The energy source for the brain must also be intact. "Black boxes" do not work in groups unless the components are properly aligned. Malformations do sometime result in defective mentation.

Since these statements are as valid as any other current suggestions, it is necessary to include these anatomical changes in any consideration of pathogenesis in the patients called "schizophrenic."

SUMMARY

Pathological and clinical findings were reviewed in 50 schizophrenic patients. Only 2, both alcoholics, had no notable pathological brain abnormalities. Vascular diseases and malformations of the brain were particularly frequent. The diversity of findings was a prominent feature, and tended to support the thesis that schizophrenia is a syndromic diagnosis. The series suggests that some of the findings may be causally related to the schizophrenic symptoms.

URINARY EXCRETION OF TRYPTOPHAN METABOLITES BY SCHIZOPHRENIC INDIVIDUALS

F. CHRISTINE BROWN, Ph.D., J. B. WHITE, JR., B.S., AND J. K. KENNEDY, M.D.¹

In 1951, Young, *et al.*(1) reported that schizophrenic individuals excrete larger quantities of a material which couples with diazotized sulfanilic acid than do normal individuals. McGreer, *et al.* (2, 3) have published similar findings. All these studies utilized qualitative paper chromatographic procedures. Recently, nicotinamide has been implicated in the schizophrenic process by the report of Hoffer, *et al.*(4) that this compound alleviates the symptoms of schizophrenia. Wooley(5) suggests that nicotinamide elicits a "tranquilizing" effect. Nicotinamide is derived from dietary tryptophan and nicotinic acid, and a large part of urinary aromatic amines, which respond to diazotization and coupling, are also products of tryptophan metabolism. Therefore, an understanding of the significance of these observations to schizophrenia should be obtained through a study of tryptophan utilization by schizophrenic individuals.²

METHODS

Schizophrenic subjects were selected for this study by the psychiatric staff upon admittance to the hospital. The patients were females, Caucasian and Negro ranging in age from 17 to 36 years. They had received no drugs prior to or during the time of experiment. Controls in the same age, sex and race classes were chosen from laboratory and office personnel.

A basal 24-hour urine sample was collected from each subject. At the end of the 24-hour period, 0.4 mole of L-tryptophan per Kg. of body weight was given orally in a milkshake and a second 24-hour urine specimen was collected. Creatinine values were used as criteria for completeness of

collection. The urine was stored at 4° C. under toluene until the analyses were completed (7 to 10 days).

Price, *et al.*(6) have shown that a constant diet is not necessary for quantitative studies on the metabolism of supplemental doses of tryptophan. Therefore, the diets of patients and controls were self-selected. However, they were cautioned to avoid excesses of food or liquids.

Five diazotizable fractions, including anthranilic acid glucuronide, o-aminohippuric acid, acetyl-kynurenine, kynurenine and an unidentified fraction were isolated from the urines by fractionation on Dowex 50 columns. Each fraction was analyzed colorimetrically by diazotization with nitrous acid and coupling with N-1-naphthylethylenediamine. The entire procedure was accomplished as directed by Brown and Price(7). Synthetic samples of the first three compounds in this group were not available for recovery experiments. Recoveries of kynurenine were 98%. Total diazotizable substance was determined on diluted urine samples.

Kynurenic acid and xanthurenic acid were isolated from Dowex 50 columns and aliquots from the eluants were analyzed for kynurenic acid fluorometrically, according to Satoh, *et al.*(8). In our hands, the procedure of Satoh, *et al.* for the fluorometric determination of xanthurenic acid was impracticable since kynurenic acid interfered. Xanthurenic acid was, therefore, determined colorimetrically by the method of Rosen, *et al.*(9), after concentration of the eluant from the Dowex 50 column. Recoveries of kynurenic acid were 90% and xanthurenic acid 58%.

Quinaldic acid(7), and N-methyl-2-pyridone-5-carboxamide(10) were determined as outlined by Price and his co-workers. Recoveries of synthetic material were 71 and 82% respectively.

All analyses on urine from subjects receiving tryptophan and on basal urines were done in duplicate. Since some of the

² We are indebted to Doctor R. F. Corder of the University of Tennessee, Department of Psychiatry, for the statistical evaluation of the data presented. We also wish to thank Doctor J. L. Warnell of the DuPont Company for generous supplies of L-kynurenine.

methods gave low recoveries of added synthetic material, internal standards were run with each analysis and the results corrected accordingly.

DISCUSSION

The data obtained from the described experiments are shown in Table 1. Metabolic excretion varied widely from individual to individual and this tendency was most evident after the subjects had received a test dose of tryptophan.

Statistical evaluation of the data in Table 1 was accomplished through the small sample, nonparametric rank test (Wilcoxon T Test)(11) using a confidence level of 1%. With the exception of the excretion of N-methyl-2-pyridone-5-carboxamide, no significant differences in the excretion of metabolites by patients and controls were observed. The excretion of N-methyl-2-pyridone-5-carboxamide by patients not receiving tryptophan was shown to be significantly less than the normal controls. No significant differences in the excretion of this compound by the two groups were observed after an oral dose of tryptophan.

Interpretation of data collected from studies on schizophrenics is difficult and as Kety(12) has so elegantly pointed out, the sources of error are wide and sometimes subtle. With these limitations in mind, two possible explanations for the observed excretion pattern of N-methyl-2-pyridone-5-carboxamide are worth considering. The decreased basal output could be due to dietary factors which are obscured by supplementing tryptophan. N-methyl-2-pyridone-5-carboxamide is the chief degradation product of nicotinamide and the pyridine nucleotides, all of which are derived from dietary tryptophan.

On the other hand, the mechanism by which nicotinamide and its derivatives are converted to the pyridone may be malfunctioning in schizophrenics. This idea is difficult to reconcile with the data obtained from patients and controls after an oral dose of tryptophan. If the assumption is made, however, that the degradation of nicotinamide is inhibited in the schizophrenic,

a large oral dose of tryptophan could overcome the inhibition and obscure the differences noted in the basal urines. In view of the work by Woolley and Hoffer, *et al.*, mentioned previously, the latter hypothesis deserves further investigation.

Under the experimental conditions reported here, no significant differences were found in the excretion of diazotizable compounds by schizophrenic patients as compared to normal controls, either at the basal level or after oral doses of tryptophan.

SUMMARY

Urine from schizophrenic patients and normal controls has been analyzed for metabolites of tryptophan, before and after oral doses of this compound. With the exception of the basal excretion of N-methyl-2-pyridone-5-carboxamide, no significant differences in the urinary excretions of tryptophan metabolites has been found.

PROBLEMS IN APPLICATION OF THE BASIC CRITERIA OF SCHIZOPHRENIA

HOWARD N. COOPER, M.D.¹

INTRODUCTION AND BACKGROUND MATERIAL

From 1885 to 1897 at the psychiatric hospital in Rheinau, Switzerland, and subsequently at the Burgholtzli, Eugen Bleuler's talents turned to a quarter century of scholarly observations which in 1911 culminated in his classic monograph on the group of schizophrenias (1). The half century since has magnified the importance of this work to the therapist because it permits of diagnosis and intervention before the patient disorganizes to the point of blatant symptomatology.

As a result, steadily increasing numbers of cases have been diagnosed as schizophrenic as the decades have passed. The more sophisticated the setting, the more academic the hospital, the more trained and experienced the psychiatrist, the greater is the tendency to observe the more subtle manifestations of Bleuler's 4 fundamental symptoms: thinking difficulty re: continuity of associations, affect disturbances, autism, and ambivalence.

The following questions arise: Is there a point of diminishing returns? If a given patient is sufficiently "well-organized," i.e., of sufficient "ego strength" so that one must strain at subtle nuances in order to establish a schizophrenic diagnosis, then how valuable is the diagnosis for all descriptive, categorical, therapeutic, and prognostic purposes? In short, are all patients who pass the test on the 4 fundamental criteria (regardless of how low the score) really candidates for manifesting the "accessory symptoms" of further deterioration?

THE CONCEPT OF MEANINGLESS DIAGNOSIS

In general the clinician is interested in the diagnosis of schizophrenia in order to help answer certain questions about the patient (2, 3, 4): 1. His reality testing. 2. Therapeutic technique required. 3. Length of treatment and goals of therapy. 4. Po-

tential for disorganizing. 5. Prognosis. Do all patients now considered schizophrenic by private therapists, have notably faulty reality testing? Do all patients who show Bleuler's fundamental symptoms, however mildly, thereby require radically different therapeutic approach, or merely individual variations as treatment progresses, as is true of all other cases? Does a patient with chief complaint of uncomfortable anxiety, who gets classified as schizophrenic only after several weeks of careful observation, necessarily require lengthier treatment than a chronic obsessive-compulsive? Or should the goals be less ambitious? Should such a person invariably be considered a prospect for disorganization? Is prognosis markedly changed by the new "findings"? If in the categories of schizophrenia we include individual cases for which we must answer the above questions in the negative, then that diagnosis begins to lose meaning for the clinician.

Fortunately, most experienced therapists circumvent the issue by evaluating each individual patient on each individual question. It is possible that the most feasible method of diagnosis in these cases is the one or two paragraph description of psychopathology.

THE PROBLEMS OF DIFFERENTIAL DIAGNOSIS

In addition to the chances of meaningless diagnosis there are the pitfalls of misdiagnosis:

1. The association difficulty (5): In schizophrenia the loosening of associations is due to distraction from below. Reality is not real enough to command full attention without a tremendous cost in energy. The "ego" is not strong enough to keep unconscious symbolisms and tangential associations from constantly coming to the fore and interfering. Hence the "blocking," the "eccentricity," and the difficulty of understanding verbal and behavioral productions of the severe schizophrenic. In less severe cases, this thinking difficulty due to dis-

¹ Chief of Mental Health, Alameda County, Calif.: Highland Hosp., Oakland, Calif.

traction from below may be confused quite easily with non-schizophrenic concentration difficulty due to distraction by anxiety, fear, tension, or preoccupation. In fact it may be impossible to differentiate the two concepts.

2. The affect difficulty(6) : In the schizophrenic it may be a good deal less apparent than in the depressive or the hysteric, and a good deal less "inappropriate" than in the case of the "nervous laugh" or the affect displacement.

3. Autism(7) : Frequently this represents the phenomenon of the injured creature retiring to a corner to lick his wounds. The "autism" thus found in reactive tension or depression may be almost impossible to differentiate from the watching-of-the-show-within of the schizophrenic. At any rate, this symptom usually is associated with the clinical picture of "introversion," whereas many schizophrenics are "extra-verts."

4. Ambivalence(8)* : In the schizophrenic this theoretically results from trouble with control of questionable or unacceptable desires or ideas, with resulting apparently impulsive or contradictory behavior, verbalization, or feelings. In less severe forms of the illness it is almost impossible to differentiate from all the other forms of ambivalence so common in the human experience.

Therefore, we may say that the more the clinician must strain to establish the diagnosis of schizophrenia, the greater becomes the danger not only of meaningless diagnosis, but of misdiagnosis as well.

CASE HISTORIES

I should like to illustrate with the case histories of 4 patients I treated while in practice in New York City during the past 7 years.

Case 1.—A.B. presented with chief complaint of insomnia, tension, and preoccupation with encroaching baldness. He was a 26-year-old unmarried white accountant; the youngest of 4 siblings, and only male child of an authoritarian policeman and a would-be ballerina. In therapy with one psychiatrist 5 months, he discontinued because discussion was getting close to uncomfortable sexual material. He then undertook treatment with a second psychiatrist for 4 months, but this time stopped because no

uncomfortable areas were touched and therefore "the doctor must be incompetent." Both diagnosed schizophrenia, one "paranoid, ambulatory," and the other "mixed, incipient."

I perceived associational thinking difficulty during the first 35 interview hours. Furthermore, although A.B.'s intelligence was well above average, his handling of abstract conceptualization (proverbs, categories, and comparative definitions) on clinical psychiatric examination scored as poor. Minnesota Multiphasic Personality Inventory test scored plus 36 (T-score 75) on schizophrenic scale with good reliability and validity indices. Preoccupation with hair loss impressed me as obsessive and perhaps delusional. Hairline and thickness were well above average. (Later comparison with photographs showed there actually had been a very slight but even recession of hairline over a 3 to 4-year period, so I could not quite call this preoccupation a delusion.) He would display strong anger when discussing certain minor activities either of his employer or of his girl friend. These reactions appeared inappropriate by all external yardsticks but quite appropriate in terms of the patient's own inner associations. A.B. admitted having no close male friends. He would sit in his lounge chair for hours on end immersed in a rich and grandiose fantasy life. He displayed marked ambivalence toward the few important individuals in his ken: family, employer, and girl friend. I concurred in the diagnosis of schizophrenia.

Then during the fifth month of our association, the following happened within a 3-week period: 1. A.B.'s girl friend left him after an argument in which she cast aspersions on his virility, and 2. He was the only employee in his department who received no Christmas bonus. These events hit upon dynamically sensitive areas: the questions of virility, rejection, and fear of authority. He reacted with a noticeable increase of tension and depression but no essential change in fantasy life, no inability to work, no deterioration of behavior, no clinical increase of thinking difficulty, and no significant change in schizophrenic scale of the MMPL. Exploration showed that these events did function to provide some masochistic gratification, as well as to provide some reality-validation of low self-esteem. In addition, they served to release the patient from what amounted to a burden: supporting a close heterosexual relationship. Nevertheless, these ameliorating factors were minimal; the overall effect was severely traumatic. Certainly there was no paradox in the patient's reaction; he did not improve; symptomatology definitely intensified,

but not in the "schizophrenic" direction.

Three months later, before recovery had progressed to the pre-traumatic level, the following events happened to A.B. within a single month:

1. His left cheek was slashed for a length of four inches by street gangs. A scar was inevitable.

2. He lost a considerable amount of his savings in the stock market decline of 1957. These occurrences also hit upon dynamically sensitive areas: physical appearance, which the patient regarded as one of his few remaining assets; "castration" anxiety; and great fear of material insecurity (an important symbol). This time too, reaction was in terms of tension and depression without any change in his "schizophrenic" direction.

Looking for sources of stability one could venture that despite all these traumata, and despite difficult work relationships, A.B. did have the ego resources inherent in the day-to-day compulsive performance of his accounting job. The fact is, however, that before entering therapy, he had come through periods of unemployment which lasted as long as 6 months without any extraordinary discomfort. Also, none of these situations was continuous in the sense that supporting a family is continuous over a period of years. True, such a continuing experience might slowly disorganize a "borderline schizophrenic"; but the patient could with perhaps as much probability, develop acting-out type defenses as stress intensified, and thus reach a level of "adjustment" short of disorganization.

Case 2.—C.D. was a 29-year-old, white, commercial artist, the only child of a lawyer of limited success and a woman who married for security while still enamored of another man. Chief complaint: ambivalence *per se*. Considered a very personable girl who frequently reciprocated the interest of her many male suitors, she inevitably would suffer extreme conflict before reaching the point of matrimony. The two marriages she did consummate ended in divorce "because I always became so hypercritical." All close relationships were tenuous because they were mixed with strong antagonism. I was impressed with associational thinking difficulty during the interviews. Clinical tests of abstract conceptualization showed many spoiled responses. Rorschach examination uncovered an intense bizarre fantasy life compatible with schizo-

phrenia. MMPI test scored plus 38 (T-score 74) on the schizophrenic scale with good reliability and validity indices (hysteria score was within normal limits and patient was not especially erotic, frigid, or dramatic). There was both depersonalization and derealization. Affect appeared blunted in all directions. My diagnostic impression was of schizophrenia.

During her first year of therapy the fashion magazine which employed C.D. was discontinued. This meant loss of two emotional supports: 1. A very real job gratification and 2. Status and material symbols; her \$12,000 annual salary had enabled C.D. as a young unmarried woman to partake of many of the material graces of midtown Manhattan. After this loss she began to engage in sexual promiscuity. The therapeutic process was utilized to modify this symptom. She suffered some accentuation of tension and depression. The incident provided no ameliorating factors whatsoever. Nevertheless, there was no essential change in fantasy life, no deterioration of the routine details of daily behavior, no clinical increase of thinking difficulty, no measurable change in abstract conceptualization, no significant change in schizophrenic scale of MMPI, no observable difference in depersonalization or derealization, and no change in affect except for some depression and some anxiety over finances. For the most basic expenses her parents grudgingly came to her rescue so there was no stimulus to cope with a really intrusive reality. Any jobs proffered paid much less than her previous position. In this setting I was unsuccessful in preventing C.D. from marrying a man in his 50's (for whom she felt no attraction) frankly because he was rich. During the first 8 to 9 months of this relationship, her hypercritical tendency grew, but then reached a plateau, and a working equilibrium was established. C.D. manifested ambivalence of the usual degree and scope which she brought to all her relationships, but no more than that. She carried uncomfortable guilt feelings and moderate depression but, again, at no time displayed any change in a "schizophrenic" direction. Fantasy life, clinical thinking difficulty, Minnesota Multiphasic performance, routine behavior, abstract conceptualization, and affect range had remained constant.

Apparently, one major reason this marriage did not also end in divorce was that this husband, for reasons of his own (not the least of which was age difference) was much more tolerant of what C.D. had to hand out. Therapy continued until 1957, at which time the marriage was two years old and stabilized. A semiannual follow-up through 1959 continued

to show a "stable" situation with some lifting of the chronic mild depression and guilt.

It may be ventured that this narcissistic woman never had been threatened with loss of physical attractiveness, a factor which conceivably might disorganize her. C.D. was not physically attractive, nor was natural physical attractiveness part of her self-image. Her assets were personability, flair for wearing clothes, intelligence, and artistic talent.

Case 3.—E.F. presented with chief complaint of a multiplicity of physical symptoms, recognized by internists as well as by herself as "psychosomatic." She was a 31-year-old white housewife, the second of 3 children (and older daughter) of a small-town merchant. Her mother died when she was 3 and father remarried a year later, this time to an active business woman. E.F. had been married for 6 years to an advertising copywriter whose income was comfortable but not quite as high as that of other members of her family. The patient's symptoms, which began with the birth of her son 4 years previously, had been neuro-muscular, cardio-vascular, respiratory, gastro-intestinal, and dermatologic. A reputable psychological testing service had administered to her a complete diagnostic battery before she started therapy and concluded that E.F. was an "early schizophrenic." This battery was compounded of clinical psychiatric examination, MMPI, Rorschach, and Thematic Apperception Test. I obtained a Minnesota Multiphasic score of 46 (T score 86) on the schizophrenic scale with good reliability and validity indices. Clinical examination of abstract thinking showed spoiled response to proverbs testing, and poor handling of categories and comparative definitions. Judgment was poor. Overt anxiety was minimal; concentration was adequate; nevertheless, there was much blocking on many topics. Affect appeared blunted. The first 30 interview hours strengthened my impression of associational thinking difficulty. In addition, there were periods of actual rage whenever discussion turned to certain locations, dates, acquaintances, or events. This rage was appropriate only in terms of the sudden reality of her own associations. E.F.'s impulsive reversibility on almost any issue on which she happened to take a strong stand, early observed in interviews, was confirmed by her husband and by the patient herself. I concurred in the diagnostic impression of schizophrenia.

During E.F.'s second year of therapy, her son contracted a case of poliomyelitis which

left him with residual quadriceps, peroneus, and tibialis impairment. Because of tremendous ambivalence toward the child, she reacted with great guilt. However, during the acute stages of his illness, E.F. was too distracted by the demands of reality to show an intensification of psychopathology. As acute illness gave way to chronic infirmity, she became more and more depressed. Somatic symptoms decreased as depression increased. I had anticipated this sequence as part of a well-known road to schizophrenic disorganization. Nevertheless, at no time did Minnesota score change significantly, nor did clinical examination of abstract thinking. There was no deterioration of behavior, no change of fantasy content, no perceptible change in thinking difficulty, no increase of frequency or intensity of inappropriate rage and no noted increase of ambivalence as gauged by the "impulsive reversibility" of her attitude to people and issues. The only augmentation of psychopathology was in the non-schizophrenic realm of depressed mood, retardation, and non-psychotic self-depreciation.

After 4 months, depression began to lift and somatic complaints began to return. (The latter faded in due course of therapy over another year.)

When her son contracted poliomyelitis, E. F. had been in therapy for over a year, thus having established enough of a therapeutic relationship to permit either the working through or supporting of a crisis which otherwise might have led to disorganization. But it must be pointed out that adverse changes did occur despite the therapeutic relationship, that at first these changes did look like the approach to overt schizophrenic symptomatology, but were confined completely to non-schizophrenic manifestations instead.

Case 4.—G.H. presented with chief complaint of impotence, of one-year duration. He was a 31-year-old white sales executive, with Stanford Binet score of 120; the older of two children (and only son) of a housemaid who had been widowed since the patient was 4 years old. G.H. started out as a studious boy but never finished high school, in part because of family financial pressures, and in part as an over-compensatory surrender to his anti-intellectual "civil-service-and-baseball" lower income urban milieu. At 22 he married a nurse one year his senior; the couple had 3 sons and 1 daughter. She was a "sweet" woman who

came from the same socio-economic background as the patient, but also shared his intellectual tastes.

I perceived an associational thinking difficulty during the first 25 hours of therapy. Clinical examination of abstract conceptualization scored poorly. MMPI tests scored 40 on schizophrenic scale (T score 84) with good reliability and validity indices. Frequently, G.H. would be distracted by sudden strong emotions associated with ordinary daily events. For example, he came home from the office one evening after submitting an expense sheet which was slightly more "padded" than usual. Upon entering, he happened to glance at the "rabbit ears" television antenna and suddenly was overcome with fright. Subsequently, it came to mind that the reason for this fright was an association of the antenna to the two punitive arms of an avenging authority. On another occasion while pulling the lever of a cigarette dispensing machine, G.H. was suddenly engulfed by depression. Several minutes later it occurred to him that the reason for this depression was that the last time he used this machine, 4 years previously, an unpleasant episode took place on the same day.

The symptom of impotence in itself proved to be most immediately involved with strong feelings of ambivalence toward his wife. Fatigue was a problem, and it was disclosed that maintaining an extravert façade for his sales executive position cost G.H. copious amounts of energy. Furthermore, it was the only self-image which was acceptable. He stated that he spent many hours alone in fantasy (of grandiose content). My diagnostic impression was schizophrenia.

Early in his second year of therapy G.H.'s corporation changed administrations. G.H. was demoted in position and pay, a factor which traumatized the dynamically sensitive area of "castration" anxiety and acceptance of identity. There were no ameliorating factors because the new position demanded just as much façade responsibility, and expenditure of energy. The patient reacted with tension for 3 months and then depression for another 4. During this period of reaction there was no observable change in thinking difficulty, in abstract conceptualization, in Minnesota Multiphasic score, in intensity or content of fantasy life, or in ability to work. There was no noted deterioration of behavior or increase of frequency or severity of episodes of inappropriate affect. Ambivalence toward his wife remained on an even keel for the time being. In short, G.H. did sustain increase of psychopathology

as a reaction to a traumatic situation, but not at all in his "schizophrenic" area.

CONCLUSIONS AND SUMMARY

Four cases were diagnosed as schizophrenic by careful observation and documentation. The patients had the following in common :

1. By all symptoms no schizophrenia was immediately apparent. It required time and attention to establish the diagnosis in all cases. But then it remained firmly established by the basic accepted criteria.

2. The patients were persons of good intelligence and had other assets as well. They tended to mobilize many mechanisms of defense as "ego" structure threatened to "weaken" further. These consisted both of additional neurotic defenses and some tendency toward "acting-out," but no change was manifested in areas considered schizophrenic.

Therefore, we are considering a category of individuals who belong to the group of schizophrenias according to legitimate definition, but apparently no more capable of disorganization, or display of blatant "accessory" symptoms, than the next person.

In each of these instances, schizophrenic psychopathology comprised one part of the total picture, but did not thereby characterize the case. This concept differs from Hoch's "pseudoneurotic schizophrenia" (9) in that the latter describes an illness which is schizophrenic for all important clinical purposes : disorganization potential, therapeutic technique required, goals of therapy, and prognosis. By way of contrast, perhaps the best diagnostic approach to the above "pseudoschizophrenic neurotic" cases is the one or two paragraph description of psychopathology, with all factors evaluated on an individual basis.

CLINICAL NOTES

METHOXYPROMAZINE IN CHRONIC SCHIZOPHRENIA

MAX APFELDORF, Ph.D., HANS G. BAUER, M.D.,
AND THOMAS H. MCGAVACK, M.D.¹

Eighteen chronic schizophrenic men, median age 62, were subjects of a double blind study of the effects of methoxypromazine on adjustment.

Evaluation of the patients was accomplished with 6 periods of evaluation: 1. A baseline period of 3 weeks in which the patients were maintained on their previous regime, 2. A drug free period of 5 weeks, 3. An experimental period of 9 weeks in which half the patients received active methoxypromazine and half received placebos, 4. A second experimental period of 6 weeks in which those subjects who had received placebos received the active drug and *vice versa*, 5. A drug free period of 24 days, 6. A third experimental period in which those who received placebos in the second experimental period were given the active drug and *vice versa*.

The daily doses all given orally ranged from 150 to 600 mg., but none was below 300 mg. during the second and third experimental periods. Increases of dosage were made at one to two week intervals.

The quantitative evaluation was accomplished with a variety of techniques and tests. A series of rating scales, called the Ward Adjustment Scale, were adopted and modified for use with our particular chronic hospital patients from such charts as the Lorr Multidimensional Scale.

A weekly rating form tapping three facets of patient behavior was devised: 1. Facial expression, 2. Patient's attitude toward personnel, and 3. Cooperation. This was used by the physician on weekly rounds and by the nursing assistant.

Various psychological tests and techniques were also employed. The Porteus

Maze Test was selected as measuring foresight or planning ability. The Picture Discrimination Test assessed a form of judgment usually deficient in schizophrenics. The Color Naming Test was used to determine changes in mental speed. Standard questions on orientation for time, place and person were also asked by the nursing assistant and responses to these were quantified.

RESULTS

Though 18 patients were initially selected for these studies, only 12 were able to complete them. Two became seriously ill and 4 developed severe problems in adjustment.

Except in the third experimental period, statistical analysis of the data from the remaining 12 subjects failed to yield any evidence of improvement while taking methoxypromazine. In this period, patients taking methoxypromazine scored somewhat higher on the Ward Adjustment Scale than those receiving a placebo. This indicated that they were manifesting more psychological and somatic symptoms than the control group.

No significant unpleasant symptoms or side effects were observed in any subject. There were no abnormal fluctuations of pulse, temperature, blood pressure or weight which could be attributed to the drug. In the following laboratory tests completed weekly, no abnormal findings appeared: urinalysis, serum bilirubin, and complete blood count.

The present findings are consistent with those of other observers, and indicate that chronic schizophrenics are less responsive than acute schizophrenics to the therapeutic action of tranquilizing medications.

SUMMARY

No appreciable change in adjustment was

¹ From the VA Center, Martinsburg, W. Va. The drug and placebos were furnished through the courtesy of Lederle Laboratories under the trade name, Methopromazine.

noted in 12 chronically ill schizophrenics who were subjects of a 6-month double blind study with methoxypromazine. No

toxic or untoward side effects were noted with doses ranging from 100 to 600 mg. daily.

ADJUVANT THERAPY WITH ISOCARBOXAZID¹

STANLEY R. DEAN, M.D.²

Iproniazid³ has been markedly effective as adjuvant therapy in mild and moderate depressions (1-4), but its toxic and side effects (5-6) led to the search for a less toxic but equally or more effective analog. Isocarboxazid, a new agent reported to have up to 30 times the potency of the parent compound (7), seemed to meet these requirements (8). Several investigators reported improvement, with a minimum of side effects, in a large proportion of their patients. The reports were so encouraging that we initiated a trial study in the office treatment of 47 patients.

Our series, composed of 7 males and 40 females ranging in age between 17 and 74 years, was divided into 4 categories: reactive depressive, schizophrenic apathetic, manic-depressive (depressed), and obsessive-compulsive. These syndromes had been present for several weeks to several years.

Dosage of isocarboxazid was individualized, beginning with 10 to 40 mg. daily for 2 weeks to 3 months, and either maintained at the same level or reduced as patient response indicated. Treatment in 41 patients was continued for 1 to 8 months, while 6 were treated for less than 1 month.

Isocarboxazid did not replace any of the therapeutic measures being employed at the start of the study, but in all cases was added to the regimen, which included other chemotherapy for some patients, intensive psychotherapy and hypnobarbital (with hexobarbital sodium and methamphetamine HCl) for all, and ECT when considered necessary.

Patients were given routine medical examinations at the beginning of treatment and at specified intervals thereafter. Although

none had a history of liver or kidney disease, they were observed for clinical indications of liver involvement.

The degree of improvement was judged in the light of our many years of previous experience with similar cases. Taking into consideration the complete therapeutic picture, results with the test drug were judged as excellent, good, fair or poor.

Thirty (63.8%) of the 47 patients had a positive response to isocarboxazid. This is consistent with improvement (approximately 68%) in the general category of "psychiatric conditions" calculated as the average for some 3,000 patients in previous studies (9).

Since the drug was effective in 26 of the 27 reactive depressive and schizophrenic apathetic patients, it would appear to be a specific agent for these conditions. However, since there were only 4 schizophrenic apathetics, no definitive conclusions can be drawn for this group, and it should be noted that while their mood and cooperation improved, disturbed thought content was not affected.

In contrast, the drug was judged favorably in only 4 of the 20 manic-depressive and obsessive-compulsive patients. No better results have been obtained with tranquilizers, and further search for an effective chemotherapeutic agent for this type of patient is definitely needed.

There was a general tendency toward lowering of blood pressure, often beneficial, with a return to normal when dosage was reduced. Three patients discontinued medication because of "nervousness" and one was taken off the drug after 2 weeks because of orthostatic hypotension. One other developed hypotension which responded to interruption of treatment and a subsequent reduction in dosage; one became constipated; 2 developed edema which was rou-

¹ Marplan, trademark of Hoffmann-La Roche, Nutley, N. J.

² 122 Forest St., Stamford, Conn.

³ Marsilid®, Hoffmann-La Roche Inc., Nutley, N. J.

tinely managed with diuretics and reduction of dosage. One obsessive-compulsive who was also an alcoholic regressed, a development that very likely would have occurred under any circumstance.

Fifteen patients who had previously been underweight gained an average of 8 pounds. No dose-effect relationship was observed. In conjunction with hypnonarcosis, isocarboxazid caused moderate to severe headaches in most patients. This has not been reported in other studies with isocarboxazid and should not be considered a potential side effect when the drug is administered alone.

SUMMARY

In this series of 47 patients with a variety of depressive reactions, isocarboxazid produced a fair to excellent effect in 63.8% overall, and in 26 of the 27 reactive depressives and schizophrenic apathetics. Although it did not eliminate nor reduce the need for ECT, it was a valuable adjunct to ECT and intensive psychotherapy, particularly in reactive depressions. While not

found quite as effective as iproniazid, it was definitely better tolerated and less toxic, with no clinical evidence of hepatotoxicity in any of the patients.

RAPID INTENSIVE TREATMENT OF IMPENDING RELAPSE

HERMAN C. B. DENBER, M.D., AND PAUL RAJOTTE, M.D.¹

We have observed that the usual methods of treating impending relapse are inadequate or unnecessary. Patients are formally readmitted and usually stay 3-6 months or longer. Many feel after a time that it is useless to leave the hospital for they always "come back anyway." Since we were studying 50 patients in a special research follow-up clinic, it was not difficult to discern the initial symptoms of a new psychotic episode. It was found also that some patients would spontaneously ask for "a rest" because they "weren't feeling too well."

THE PLAN

Patients showing a recrudescence of symptoms that led to their original hos-

pitalization were asked to stay in the ward for a 5 day period during which time they would receive intramuscular drugs daily and take part in the regular ward program. A remission of symptoms during this period made further in-hospital treatment unnecessary. If there were only a moderate improvement (still requiring further treatment), they would spend the week-end at home and return for a second period. At the end of this time, they were either formally readmitted (symptoms unabated), or else left the ward (remission).

This report concerns 15 patients, 11 of whom were between 20 and 40 years of age; 14 were schizophrenic (11—paranoid; 3—catatonic). Nine had 2-3 previous hospitalizations; three had 4 previous stays, and three had 5 or more admissions. Nine patients had been hospitalized one year or less prior to placement on convalescent care; one for 1-2 years, and five more than

¹ Research Division, Manhattan State Hospital, Ward's Island, New York City 35, N. Y., and College of Physicians and Surgeons, Columbia University, New York, N. Y.

2 years. All were on convalescent care less than 9 months before threatened relapse required the intensive treatment described above.

METHOD

Thioperazine (7 cases), prochlorperazine and chlorpromazine (3 cases), fluphenazine (3 cases), chlorpromazine (1 case), and imipramine (1 case) were the drugs used. The intramuscular route was the choice of administration. Anti-Parkinson drugs were used where necessary. All patients took part in the ward and social therapy program.

RESULTS

Eight patients had one single treatment period, ranging from 1-6 days with a mean of 4.5 days. One spent 4 consecutive weekends in the ward, and 6 had two successive periods of treatment, each ranging from 3 to 8 days.

Eight patients voluntarily requested admission under this program ("I'm sick again"), and all left the hospital in remission. Seven were required to stay on the physician's or family's request. Only 3 in this group were able to leave; 4 had to be readmitted.

Discontinuation of medication was the presumed cause of the threatened relapse in 9 patients; all 4 readmissions were in this group. In 5 cases, added environmental stress and/or insufficient drugs were deemed the precipitating effect. In one case, no cause could be assigned.

There were no episodes of destructiveness or aggressiveness in spite of the fact that some patients were actively hallucinating. There were no untoward drug reactions.

The follow-up ranges from 4 weeks to 6 months, without any further change in status.

DISCUSSION

The importance of continued chemotherapy is again stressed in this study. One patient (with 4 hospitalizations) who experienced unusually severe extra-pyramidal symptoms on drug therapy said, "I'm coming back to the hospital. I'm sick again be-

cause I did not take the pills." Another with 4 readmissions, the last for 27 months, relapsed in 5 months and again in 7 months, having stopped her medicine each time.

Ten of the 15 patients showed signs of relapse between the fifth and seventh months. Therefore, special attention must be given to outpatients at this time. The shortest period of convalescent care before threatening symptoms appeared was 5 days and the longest 9 months. In the first case, the patient left the hospital at the same time the physician went on vacation, her medication was decreased and there were many marital problems. In the second case, 5 weeks after voluntarily having discontinued her maintenance medication, there was a full recurrence of the paranoid symptomatology. The patient was violently opposed to the idea of returning to the hospital, but relented when this was proposed finally as a solution. She left 4 days afterwards in a full remission.

Since this plan has been in operation, the patients feel that a return to the hospital will not last "forever," and very frequently spontaneously ask for treatment. Separation of the patient from the household breaks a reciprocal relationship where anxiety and tension mount on both sides. The family soon demands hospitalization, and then very often the patient actually develops acute symptoms. Our method attempts to avoid this process.

The observations suggest that signs of incipient relapse can be treated in the intensive manner described, obviating prolonged hospitalization with their attendant "hospital-induced" symptoms.

The 11 patients returning to the community stayed in the hospital for a total of 71 days. Assuming that the relapse would have required rehospitalization with an average stay of 135 days, then under ordinary circumstances this group would have been hospitalized for 1,485 days.

CONCLUSION

Rapid intensive in-hospital chemotherapy of incipient relapse can prevent a psychotic breakdown in the majority of cases.

A COMPARATIVE TRIAL OF ECT AND TOFRANIL

E. M. BRUCE, M.B., N. CRONE, M.B., G. FITZPATRICK, M.D., S. J. FREWIN, M.B.,
A. GILLIS, M.B., C. F. LASCELLES, M.B., L. J. LEVENE, M.B., AND
H. MERSKEY, B.M.¹

We have attempted to estimate as far as possible the relative value of Tofranil and convulsive therapy in depression. Fifty consecutive admissions suffering from depression and judged to be sufficiently ill to require ECT were given either ECT or Tofranil by random allocation. Forty-nine of these patients had endogenous depression. Those given Tofranil received doses rising to 75 mgms. t.d.s. followed by maintenance doses of 50 mgms. b.d. or t.d.s., or less if they were responding well. Those given ECT had an average of 6.1 treatments in the first month. Barbiturate sedation was used as required in both groups. Assessments were made at one month and three months.²

RESULTS

One patient refused ECT. Of the remaining 49, 42 completed a month's treatment in their original group. In 7, the response to Tofranil was too slow in the opinion of the responsible clinician to justify withholding ECT and these patients as well as one who had an anaphylactic reaction to the drug after 23 days, were given ECT.

Of the 22 patients treated only with ECT, 21 were very much better after one month and 18 of the 19 patients treated with Tofranil were also greatly improved or recovered after one month. These results show a good response to either treatment although perhaps the degree of improvement appears to have been rather better in the ECT group. If the 8 patients whose initial treatment was interrupted are also placed

in the original groups from which they were withdrawn and classed as failures of their original treatment the trend favours ECT, the differences being statistically significant ($\chi^2=4.348$, $P<0.05$). However, only 3 of the 7 who were given ECT after Tofranil got better quickly, from which it may appear that if a patient does not respond to Tofranil he is more likely to belong to the small group which is resistant also to ECT.

Another way of treating these findings would be to say that each patient who had both Tofranil and ECT during the first month should be classed as a success or failure for each of the treatments. In that case a nominal 24 patients responded to ECT and 16 to Tofranil, 6 patients failing to respond to ECT and 11 failing to respond to Tofranil. For this arrangement of the results which is perhaps the most objective the differences between ECT and Tofranil are not statistically significant. Further the time taken for treatment in hospital with ECT or Tofranil was virtually identical.

Age distribution and the response to treatment showed an equivalent degree of success from either treatment at any age.

In both the pure Tofranil and pure ECT groups all but 3 of those who had improved after one month were well at three months. Of the 8 who had had Tofranil and ECT during the first month, however, only 4 were well after three months. Of the remainder, one other had committed suicide after leaving hospital against advice.

CONCLUSIONS

The proportion of patients who improved during the first month of treatment was higher in the group given ECT but over 60% of those given Tofranil showed a good response in that time, perhaps justifying the view that Tofranil may often serve as a substitute for ECT.

² This work has been assisted by a grant for secretarial expenses from the Scientific and Research Committee of the Newcastle Regional Hospital Board and by a supply of Tofranil tablets from Messrs. Geigy Ltd.

We also wish to thank Mr. G. Coulthard, Group Pharmacist and other members of the hospital staff for their willing assistance.

UNRELATEDNESS OF MECHOLYL CHLORIDE AUTONOMIC REACTION INDICES

DAVID PEARL, Ph.D., and HARRY VANDERKAMP, M.D.¹

In the past few years, disenchantment has set in with the use of mecholyl chloride as a prognosticator for clinical improvement in mental illness. Recent reports have questioned the value and reliability of the "Funkenstein Test" which utilizes systolic blood pressure variations (2). The basic accuracy of systolic blood pressure changes has been questioned since such changes are influenced by many extraneous variables (2, 3). Funkenstein's categorization of subjects into 6 groups based on the shape and area of graphed blood pressure changes has also been found unsatisfactory. Thus, some have resorted to grosser groupings, e.g., hypo, normal and hyperautonomic nervous system reactivity as defined by the area enclosed by systolic changes over the observation period (1).

Elsewhere (6) we have stressed the greater reliability and prognostic usefulness of pulse rate indices. In a further study, the mecholyl test was given to 100 newly admitted psychiatric patients. Basal blood pressure and pulse rate readings were taken and changes over a 15 minute period were obtained instead of the more customary 24 minute span. It had been determined that pulse rate area for the shorter span correlated .94 with the longer period. Three subjects were prematurely terminated with atropine due to the severity of their reaction. Eighty-two of the remaining subjects were schizophrenic patients. Data was graphed and the correlation of pulse rate and systolic blood pressure areas was found to be -.10, not significantly different from a chance or zero relationship. The criterion of pulse rate deviation at 7 minutes, previously found to be the best single prognostic indicator (6) also correlated -.10 with systolic area. The two pulse rate measures were highly related, correlating .86.

The lack of relationship of pulse rate and systolic blood pressure variables was corroborated on a second independent sample of 50 cases. On this, systolic blood pressure area correlated with -.03 with pulse rate area and -.02 with pulse rate deviation. Pulse rate deviation correlated .84 with pulse rate area.

Obviously then, pulse and systolic blood pressure variables following a mecholyl chloride injection do not tap the same process. It is suggested that pulse rate variables may be more useful for predictive purposes and may tap more significant parameters than does the systolic blood pressure measurement. An illustration is provided in a recent study of perception utilizing tachistoscopic presentation of a perceptual span test to 53 subjects also given the mecholyl test (4). Pulse rate area and Perceptual Span score correlated .42, significant at the $P_{.01}$ level of confidence, whereas Systolic Blood Pressure Area had a chance correlation of -.19 with Perceptual Span. Thus a pulse criterion of autonomic reactivity was related significantly to an important aspect of human functioning, whereas the more usually utilized systolic blood pressure variable failed to show any relationship.

CASE REPORTS

GILLES DE LA TOURETTE'S DISEASE

JEROME M. SCHNECK, M.D.¹

Gilles de la Tourette reported on *maladie des tics* in 1885. It consists of many involuntary movements and coprolalia. Echolalia and echokinesis may be present. Patients have been described recently by Ascher (1), who reviewed the literature, and by Eisenberg, Ascher, and Kanner (2). Cases are reported infrequently.

An 18-year-old girl exhibited involuntary, explosive movements of head, neck, body, and limbs. She tossed her head backwards or to the side. Arms jerked away from or against her body. She emitted uncontrolled shrieking sounds, barking and sneezing noises. "Shit" and "fuck" were exclaimed repeatedly, without control.

She was affable in early childhood. At age 5 she had episodes of knee-bending. At 8, after her sister was born, she had temper tantrums that improved during brief psychotherapy. At 9 present mannerisms started. Her schooling was obtained at home under special arrangements.

In her speech, the patient now introduced comments with an explosive "yeah!", clicked her tongue, and ground her teeth. Her body would flex or extend with jolting thrusts. In the past, the right or left leg would bend suddenly at the knee and result, at times, in falling. Movements disappeared during sleep.

The patient had several medical contacts for psychotherapy and pharmacotherapy. In reports received, Gilles de la Tourette's disease was apparently not specifically diagnosed and perhaps not recognized. She believed symptoms increased during one period of psychotherapy. Barbiturates, benzedrine, thorazine, and other medications were of no avail. Thorazine may have made her worse. General physical and neurological examinations were negative. Electroencephalograms were normal. Bilateral chemothalamectomy had once been recommended.

In psychotherapy over several months the patient was friendly and loquacious, but superficial and evasive. Conflict areas were avoided by her. She was repressed and sexually im-

mature. She argued much at home with her sister and mother, yet denied significant feelings of hostility. She requested hypnotherapy. With stress on hypnotic relaxation, movements decreased or disappeared. When verbalization was encouraged, voluntary and involuntary movements returned. Posthypnotic suggestions apparently resulted in fewer movements between sessions but there was no remarkable change. Feelings of anxiety appeared to increase as movements diminished. Her mother was seen in consultation and the patient asked to be present. She showed no reaction to her mother's sharp, almost sadistic criticisms. Later she denied having been disturbed by them. Yet the diminution in movements obtained previously soon disappeared. The patient, having intended originally to continue longer in treatment, now expressed a desire to terminate. She wanted treatment most when her mother had hesitated. She stopped when her mother seemed to encourage it.

The multiple movements and vocal utterances seemed to be an outlet for intense aggressive feelings that were impossible for her to manage. Also, through denial, she tried to hold in check her explosive hostility. It was directed primarily at members of her family, especially her mother. It was suspected that were the symptoms to have been removed suddenly in this patient by any means, her illness might have assumed psychotic proportions.

The etiology of Gilles de la Tourette's disease is unknown. Its manifestations have been linked to hysteria, obsessive-compulsive reactions, schizophrenia, and other mental states. This patient's personality functioning suggested hysterical patterns primarily. Structural brain pathology is often mentioned but it has not been substantiated in *maladie des tics*. The prognosis is usually considered grave. Some optimism is expressed occasionally in connection with psychotherapy.

HISTORICAL NOTES

PIETRO PISANI (1760–1837) : A PRECURSOR OF MODERN MENTAL HOSPITAL TREATMENT

GEORGE MORA¹

Exactly two centuries ago, in 1760, Baron Pietro Pisani² was born in Palermo, then the capital of the kingdom of Sicily, of a rather wealthy family. After studying jurisprudence, he became interested in music and archeology. From his marriage in 1784 several children were born. Following the death of a son, a precocious musician, in 1815, he apparently underwent a long period of depression. At the end of it, when 64 years old he decided to dedicate the rest of his life to humanitarian work and therefore accepted the superintendency of the hospital for mental patients in 1824.

This hospital, originally built for lepers in the 12th century, had finally been assigned to mental patients in the 18th century. From the description left by Pisani himself, it is clear that the patients were kept in a condition of complete abandonment and that they were mistreated by the guardians. During the first three years of his superintendency, Pisani built a new hospital named Real Casa de' Matti outside of Palermo. The building was divided in two floors, for private and ward patients. Male and female patients lived in separate quarters. Among the facilities of the building were running water and many baths for about 200 patients.

In the meantime, Pisani elaborated his philosophy of treatment in the *Istruzioni (Regulations)*, published in 1827.³ Moral treatment, together with all medical technical devices, were applied in the hospital by the superintendent and his staff. This

consisted of full-time physicians and male and female attendants. Rounds were held frequently and progress and treatment notes were kept up to date. Conferences among the superintendent and the medical staff were held weekly and at the end of each patient's hospitalization. The brains of the patients who had died in the hospital were conserved in the pathological museum.

Each patient had to be committed to the hospital by state authorities and a strictly confidential personal history was taken from the relatives. After an initial bath and a visit to the hospital, the patient, accompanied by the physician, the nurse and the attendant, was given particular attention, while being carefully studied. It was Pisani's idea that "*in spite of their mental disorders, patients respond to a frank and sincere approach and are able to experience feelings of confidence, benevolence, friendship and pride.*" Particular emphasis was put on affectionate and lovable manners, which—according to Pisani—could remove the mind of the patient from his fixed ideas and turn it to good and moral principles.

Regular work, especially outside in farms or in gardens (because of the "natural inclination of man towards earth") was encouraged for all the patients, to make them relax and sleep better. They were also employed for the internal service of the hospital, and were paid a small amount of money. The therapeutic program included dances, physical exercises, songs and dramatic presentations⁴ for both male and female patients. The patients were continuously encouraged to socialize and were given progressive responsibilities, in ac-

¹ Director, Out-Patient Department, Bradley Hospital, Providence, R. I.; Research Assistant, Department of History of Medicine, Yale School of Medicine.

² A more complete and detailed study on Pisani has been recently published by the author: Pietro Pisani and the mental hospital of Palermo in the early 19th century, *Bull. Hist. Med.*, 33 : 230, 1959.

³ The exact title of this booklet is: *Istruzioni per la novella Real Casa de' Matti in Palermo*, Palermo, 1827.

⁴ For the dramatic presentations in mental hospitals in the past century, see: G. Mora, Dramatic presentations by mental patients in the middle of the 19th century and A. Dumas' description, *Bull. Hist. Med.*, 31 : 260, 1957.

cordance with their degree of improvement. This included moving around the hospital, going into town by themselves or with others, to the theatre or to shop. As Pisani believed that the cause of the patient's trouble lay in the family environment, he did not allow visits to the patients, until they appeared greatly improved. At that point, patients were sent home for a trial period of three months, and eventually indefinitely. The only systems of restriction for agitated patients were temporary isolation and tepid baths. In cases of extreme agitation, the patient was securely tied to a hammock in a specially padded room and then rocked like a child until he fell asleep. Although detailed statistics on the results of his treatment are not available today, it seems that about 160 (namely 2/5) of 400 patients treated in Palermo in 10 years were discharged as cured. This proportion of cures was superior to that obtained at Bicêtre et Salpêtrière in Paris.

In evaluating Pisani's work in its significance, it is impossible to determine today how much of it was original, and how much was influenced by contemporary views, such as those introduced by Chiarugi in Florence, by Pinel in Paris and by W. Tuke in York, England. Although Sicily was at that time in a period of general, cultural and intellectual decadence, in very poor economic condition and run by a societal hierarchy of feudal type, Pisani had travelled extensively through Europe in his youth. Furthermore, Sicily—following its "discovery" by Goethe in 1787—had been visited by a number of travellers, such as painters, writers, archeologists, or simply tourists in search of adventures, who had all introduced ideas into the island.

Whatever the question of his originality may be, the fact remains that Pisani's institution soon became the point of attraction of many visitors, who left interesting descriptions of it.⁵ In spite of the differences of background, interests and accuracy of these visitors (among whom were Lord Buckingham and Alexander Dumas the elder⁶), the

judgment on the organization, the functioning and the methods of treatment was unanimously full of admiration and of appreciation for Pisani's work. It was even suggested that different governments of Europe should use Palermo's institution as a training place to improve the condition of their mental hospitals.

More interesting for us are, however, the reports of some physicians who carefully visited the institution and left accurate descriptions of it, such as the German Edward W. Güntz in 1829⁷ and, later on, W. Mandt and Carl Rust in 1832.⁸ Because of these reports and of the novelty of Pisani's work, his name started to become known and honored in other countries. He was made a member of the Academy of Medicine of Leipzig, of the Royal Academy of London, and, in 1836, of the Boston Phrenological Society.⁹ In spite of his advanced age, Pisani continued to work until his death in 1837, during which year he succumbed to a violent epidemic of cholera while taking care of his beloved patients.

Pisani's work continued to remain alive among his contemporaries and motivated some to publish biographies of him.¹⁰ In the meantime in 1853, a psychiatric journal called *Il Pisani*, was founded, and, except for an interruption of a few years, has reappeared regularly since 1880. In the year before his death, Edward W. Güntz pub-

⁵ A. Dumas' description of the mental hospital of Palermo is in: *Impressions de voyage. Le capitain Aréna*, Paris, Calmann-Lévy, 1881, pp. 1-24. See also: *La vie d'Alexandre Dumas, raconté par A. Dumas. Textes recueillis par A. Guérin*, Paris, Juillard, 1953, pp. 213-221.

⁷ For Güntz's report, see: Güntz, E. W.: Don Pietro Baron Pisani, der Vorläufer John Conollys, Leipzig: Reklam, 1878.

⁸ For Mandt and Rust's report, see: Hoffmann, H.: Ein Beitrag zur Geschichte der Psychiatrie, *Allg. Zschr. f. Psychiat.*, 103: 76-127, 1935. Both reports contain the translation of Pisani's *Institutions*.

⁹ The document stating Pisani's nomination to honorary member of the Boston Phrenological Society was signed by Samuel G. Howe, Secretary, on April 2, 1836.

¹⁰ The most important of these biographies are the following three: A. Linares, *Biografie e ritratti d'illustri siciliani morti nel cholera l'anno 1837*, Palermo, Alleva, 1838; B. Serio, *Biografia del Barone Pisani*, Palermo, Roberti, 1839; B. Salemi-Pace, *Cenni biografici sul Barone Pietro Pisani*, Palermo, Virzi, 1878.

⁵ A special guide, written by a former patient, was printed for the visitors: *Guida pe' forestieri che si fanno a visitare la Real Casa de' Matti in Palermo*, Palermo, Muratori, 1835.

lished his important monograph on Pisani, containing also the translation of the *Regulations*. Mandt and Rust's report remained unedited for more than a century, until it was published by H. Hoffmann in abridged form. Aside from these publications, Pisani's work remained virtually unnoticed by medical historians and psychiatrists.

Only recently, after the acceptance of dynamic psychiatry, has Pisani's reform come to acquire new light and significance. Both the influence of his impressive and venerable figure and the particular suggestibility of the Sicilian population (so inclined to the acceptance of magic and of supernatural), must have created a condition especially favorable to a psychotherapeutic atmosphere. Such an atmosphere is definitely comparable to that created by other pioneers of psychiatric reforms, such as Chiarugi, Pinel and William Tuke, in spite

of the less progressive cultural and social environment of Sicily.

Pisani's principles of treatment, after a long oblivion while pathology was uppermost in psychiatry, become understandable today in the light of such recent psychiatric developments as "milieu therapy" and "therapeutic environment." Even detailed techniques, such as that of rocking the agitated patient in a hammock until he fell asleep, acquire today a new significance, in terms of the concepts of regression and of libidinous gratification.

In spite of the fact that Pisani's reforms, unlike those of Pinel and W. Tuke, were not continued after his death, his name should be remembered—especially on the occasion of the bi-centenary of his birth—among the pioneers of modern mental hospital treatment.

COMMENTS

ATLANTIC CITY MEETING HIGHLIGHTS

The 116th Annual Meeting of the American Psychiatric Association was held in Atlantic City, New Jersey, May 9-13, 1960, with headquarters at the Traymore Hotel. Business meetings and scientific sessions were held in Convention Hall. The total registration was 5,077 making this one of the largest Annual Meetings although smaller than the 1959 Annual Meeting by 27 persons. The registration included 2,434 members, 1,334 guests, 393 exhibitors, 874 wives of members, and 42 press representatives. Foreign guests included psychiatrists from Africa, Australia, England, Haiti, Italy, Japan, Poland, Portugal, Switzerland, and Turkey. The Program included 152 scientific papers and 19 Round Tables.

The official opening session was called to order by the President, Dr. William Malamud, at 9:30 a.m. on May 9. Father Doyle gave the Invocation, and a welcoming address was presented by the Honorable Robert B. Meyner, Governor of New Jersey. Following the introduction of Dr. Robert H. Felix, President-Elect, by the President, reports were presented by Dr. Mathew Ross, Medical Director; Dr. Alfred Auerback, Speaker of the Assembly; Dr. Robert S. Garber, Chairman of the Arrangements Committee; and Dr. John Donnelly, Chairman of the Program Committee. The Secretary, Dr. C. H. Hardin Branch, announced the official membership count as of March 31, 1960 as 11,037. Later at this session, 490 new Associate Members and 250 new Members were approved by the membership in addition to those members who were advanced in status. Upon recommendation by the Council, three new District Branches were approved by the membership bringing the number in the Assembly to 52: Mid-Hudson (N. Y.), Nebraska-North Dakota-South Dakota, and Ontario. Dr. Addison M. Duval, Treasurer, reported that the Association had just completed a reasonably successful year financially and that the overall financial condition had improved. Judge David L. Bazelon of the U. S. Court of Appeals in Washington, D. C. was given the

Isaac Ray Award and Dr. Albert J. Stunkard, Associate Professor of Psychiatry at the University of Pennsylvania, received the Hofheimer Prize. The winner of the 1959 Mental Hospital Achievement Award was the Somerset (Pa.) State Hospital, with Honorable Mention awards to the Philadelphia (Pa.) State Hospital and the Eastern (Okla.) State Hospital. The Presidential Address was delivered by Dr. Malamud with the response by Dr. Felix. The Opening Exercises were closed with a Benediction by Rabbi Weilerstein.

The second Business Session was called to order by the President on Tuesday afternoon, May 10, at 2:00 p.m. Dr. Evelyn Ivey, Chairman of the Board of Tellers, announced the results of the election of Officers for 1960-61 as follows: Dr. Walter E. Barton, President-Elect; Dr. D. Griffith McKerracher, Vice President; Dr. Raymond W. Waggoner, Vice President; Dr. C. H. Hardin Branch, Secretary; Dr. Addison M. Duval, Treasurer; incoming Councillors, Dr. Daniel Blain; Dr. David A. Boyd, Jr.; Dr. M. Ralph Kaufman. Proposal No. 1 to amend Article III, Section 3 of the Constitution was approved, Proposal No. 2 to amend Article V of the By-Laws was approved, and Proposal No. 3, offered as a substitute for a portion of Proposal No. 2, was defeated. Reports were presented by the three Coordinating Committee Chairmen: Dr. Harvey J. Tompkins, Committees on Technical Aspects of Psychiatry; Dr. Wilfred Bloomberg, Committees on Professional Standards; and Dr. Paul Lemkau, Committees on Community Aspects of Psychiatry. After a brief recess, the Convocation for the newly elected Fellows began with the Processional March at 3:00 p.m. A total of 162 new Fellows attended the ceremony. Highlight of the Convocation was the Fellowship Lecture presented by Leo W. Simmons, Ph.D., of Columbia University on "A Sociologist's Views on Patient Care and Treatment." The ceremony was concluded with a Recessional March.

The next Business Session was held on

Wednesday morning, May 11, and was called to order by the President at 9:15 a.m. The Secretary presented his report to the membership reviewing the actions of the Council since the last Annual Meeting. These were approved on motion from the floor. With a separate motion, the membership also approved Chicago as the site for the 1961 Annual Meeting.

The Annual Dinner was held on Wednesday evening at 7:30 in the American Room of the Traymore Hotel and was followed by a floor show and dance. Highlight of the evening was the presentation of a handsome scroll to Dr. Mesrop A. Tarumianz for his leadership in establishing the Central Inspection Board in 1948 and for his service as its Chairman since. The presentation was made by Dr. Felix and was acknowledged by the audience with prolonged applause.

The final Business Session was held on Friday, May 13, at 11:30 a.m. After he called the meeting to order, Dr. Malamud presented the gavel to Dr. Felix signifying his installation as President. The Secretary reported the actions taken by the Council at its meeting on May 12, and these were approved by the membership upon motion from the floor. Dr. Malamud presented Certificates to those who were retiring from office and indicated his appreciation to the membership and the staff for their assistance and cooperation during his tenure as President.

Other items of special interest included the meeting of the Assembly on May 9-10 for the seventh consecutive year with 49 District Branches represented. Their officers for 1960-61 are Dr. John R. Saunders, Speaker; Dr. Edward Billings, Speaker-Elect; Dr. Lester Shapiro, Recorder; Dr. Alfred Auerback, Past-Speaker; and Dr. Walter H. Obenauf, Parliamentarian. Area Members of the Policy Committee are Dr. Robert S. Garber, Northeast; Dr. William L. Holt, New York; Dr. Hamilton Ford, Southern; Dr. G. Wilse Robinson, Jr., Midwest; and Dr. G. Creswell Burns, Western.

The Adolf Meyer Lecture was presented by Sir Aubrey Lewis, M.D., F.R.C.P., of London, England at 10:00 a.m. Thursday, May 12. His subject was "The Study of Defect." The Modern Founders, who played a major part in the success of the Building Fund Drive several years ago and have continued their interest in the development of the physical assets of the Association, held their second annual luncheon on May 11 with forty members and guests in attendance. Three new Modern Founders were welcomed into the group, and each member was presented a certificate of appreciation and a rosette. The experimental Teaching Session on "Recent Advances in Biological and Cytological Genetics in Relation to Psychiatry" was well attended and well received. Admission was limited to APA members with reservations which were available without charge, and 195 members took advantage of the opportunity. A novel feature of the Annual Meeting was the "Videclinic" on Wednesday and Thursday, May 11-12, at 2:00 p.m. which utilized a large television screen and a closed circuit hook-up with Chicago and Ann Arbor to telecast the experiments of several doctors. The 116th Annual Meeting was officially closed at 5:00 p.m. on May 13.

The meeting was eminently successful both scientifically and socially and will stand as one of the finest in the history of the Association. This success was largely due to the great leadership and wise guidance of Dr. William Malamud, the retiring President, and the harmonious cooperation of the entire membership, Officers, and Committees. Special recognition and thanks should go to those who have helped in making this success possible, more particularly to Mr. Austin M. Davies, the Executive Assistant; Dr. Mathew Ross, Medical Director; and Messrs. Robinson and Turgeon of the Central Office; and members of the staff of both offices as well as the Committees on Arrangements and Program.

C. H. Hardin Branch, M.D.,
Secretary

EDITORIAL BOARD CHANGES

Dr. Walter L. Treadway, who has been an active and valued member of the Edi-

torial Board of this Journal since 1936, recently submitted his resignation, which al-

though with regret, was accepted. At the annual meeting of the Board during the 1958 convention of the APA in San Francisco Dr. Treadway was with us and we had the benefit of his discussion of the matters on the agenda of that meeting.

On behalf of the Editorial Board, I would like to express our appreciation of Dr. Treadway's services and of our long and happy associations with him.

To maintain the traditional number of members the Council has appointed Dr. Kenneth G. Gray a member of the Editorial

Board as of July 1, 1960. Dr. Gray is a qualified lawyer, with the added distinction of being a Queen's Counsel. He is also associate professor of psychiatry in the University of Toronto, and is presently serving as chairman of the Committee on Law and Psychiatry in the American Psychiatric Association. It is pleasant to record that the members of the Editorial Board were unanimous in recommending the nomination of Dr. Gray to the Council at the meeting of that body at Atlantic City in May of this year.

SOCIETY AND ART

There is no lack of folly in the Arts; they are full of inertia and affectation and of what must seem ugliness to a cultivated taste; yet there is no need of bringing the catapult of criticism against it: indifference is enough. A society will breed the art which it is capable of, and which it deserves. . . .

—SANTAYANA

SCIENTIFIC OBSERVATION

Put off your imagination as you take off your overcoat when you enter the laboratory; but put it on again, as you do the overcoat, when you leave the laboratory. Before the experiment and between whiles let your imagination wrap you around; put it right away from yourself during the experiment itself, lest it hinder your observing power.

—CLAUDE BERNARD

CORRESPONDENCE

DYNAMIC ORIENTATION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: A number of the advertisements of positions vacant for psychiatrists in the APA Mail Pouch require applicants to be "dynamically oriented." It would be wishful thinking to imagine that this meant that specially powerful or energetic applicants were wanted (*dynamis*—power, energy). What is meant apparently is that applicants should be committed to a particular theory of psychiatry.

This phenomenon, which unhappily is symptomatic of the general situation of psychiatry today, can make our profession seem ridiculous to other physicians and to scientists in general. It is a historical fact that no one theory has ever satisfactorily described

the whole material of a scientific discipline, and there is reason to believe that "psychodynamic" theory is no exception to this rule. We would surely be amused, or horrified, if biology teachers were required to be "evolutionists," or if psychologists had to be "behaviouristically oriented." Let us look at our own behaviour in the same light.

It has also occurred to me, by way of free association, that requiring applicants to subscribe to a particular theory may be an unfair employment practice, and as such could be challenged in the courts.

MARRIAGE ANNULMENT

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: On September 25, 1959, the Supreme Court of New York handed down a decision which was radically new and which is of great interest to psychiatrists.

In the case *Schaefer vs. Schaefer*, 192 N. Y. S. 2d 275, a marriage was annulled on ground of fraud. The fraud consisted in concealment of the defendant's (wife's) prior hospitalisation in a State Hospital as catatonic schizophrenic. There had been several such prior admissions, and at the time of institution of suit the wife again was admitted under this diagnosis to a hospital. There were three children to this marriage and custody was given to the plaintiff-husband. The husband had not lived with defendant as man and wife since he became aware of the facts he claimed constitute fraud.

In the past, all courts have in such cases maintained, that no fraud exists and annulment would not be granted. The courts argued, that a mental patient—whether sick, recovered or in remission—could not have committed a fraud, because fraud means intentional withholding of pertinent infor-

mation which would have prevented the plaintiff from marrying defendant had he known the true facts which were fraudulently withheld by defendant: but a mental patient is not aware of the seriousness of his disease and that it would be a valid reason for plaintiff not to enter marriage; even if recovered, the courts held, insight into the seriousness of the disease and the possibility of relapse is usually not present. Therefore fraud can not exist. The patient will usually consider his past hospitalisation as no more important than a hospitalisation for measles: once it is over it is of no further importance. This may not be true, but the defendant is not aware of it.

This principle has been completely reversed in the above cited case, and it remains to be seen, whether the Supreme courts of other states will also reverse their own previous decisions or the generally held view represented by a consensus of opinion of all experts in forensic psychiatry. The possibility that such suits may now be instituted with at least some chance of success should be known to all psychiatrists.

Hans S. Unger, M.D.,
Buffalo, N. Y.

NEWS AND NOTES

OCCUPATIONAL PSYCHIATRY NEWSLETTER.

—The Committee on Occupational Psychiatry, at its semi-annual meeting in Detroit in October, 1959, voted to establish a *Newsletter* to improve communication among those interested in and concerned with the health of people at work.

The *Newsletter*, the first issue of which bears date March, 1960, an 8-page folder, is designed to be international in scope. It will be published semiannually, or quarterly as may appear advisable. Single copies available from Mental Health Materials Center, 104 E. 25, N. Y. 10, N. Y., at \$.50.

Editor of the *Newsletter* is Alan H. McLean, M.D., I.B.M. Corp., 590 Madison Ave., N. Y. 22, N. Y.

NARCOTIC RESEARCH AT MANHATTAN STATE HOSPITAL.—A grant of \$300,000 has been made by the National Institutes of Health to the N. Y. State Department of Mental Hygiene, matched by a similar appropriation by the State, for construction of a narcotics research facility at Manhattan State Hospital.

The facility will include 20 laboratories, animal rooms, library, conference and office rooms. A 55-bed narcotic division, already established, provides both inpatient and outpatient services.

NORTH PACIFIC SOCIETY OF NEUROLOGY AND PSYCHIATRY.—The annual meeting of the Society was held in the Benjamin Franklin Hotel, Seattle, on April 8 and 9, 1960. The following officers were elected: President, Peter O. Lehmann, M.D., Vancouver, British Columbia; President-elect, Robert S. Dow, M.D., Portland, Oregon; Secretary-Treasurer, Thomas H. Holmes, M.D., Seattle, Washington; Executive Committee, Edward D. Kloos, M. D., Portland, Oregon; Wallace Lindahl, M.D., Seattle, Washington; R. L. Whitman, M.D., Vancouver, British Columbia.

HUMBOLDT UNIVERSITY, BERLIN, MEDICAL FACULTY.—The celebration of the 250th anniversary of the Charité will be held in Berlin from November 6 to November 19,

1960, in connection with the 150th anniversary of the Humboldt University. Applications for participation are to be directed to the Committee for the Preparation of the 250th anniversary of the Charité, Berlin N 4, Schumannstrasse 20-21, c/o Dozent Dr. med. habil. Dagobert Müller, secretary of the committee.

GRANT-IN-AID PROGRAM FOR ALCOHOLISM RESEARCH.

—Licensed Beverage Industries, Inc., has made \$500,000 available for a 5-year program to investigate the extent of alcoholism, its cause and treatment. Grants will be awarded to qualified researchers in the biological and behavioral sciences. It is expected that grants will range between \$2,000 and \$10,000 running for one year. Renewal of the grant may be considered. The program is administered by a Scientific Advisory Committee whose members represent a wide range of relevant disciplines. For detailed information and application forms write to the Scientific Advisory Committee of the Licensed Beverage Industries, Inc., 155 East 44th St., New York 17, N. Y.

AMERICAN ACADEMY OF PSYCHOTHERAPISTS.

—The Western Regional Chapter of the American Academy of Psychotherapists, an interdisciplinary organization, held its first annual meeting on April 23, 1960 in San Jose, California. The professional part of the meeting consisted of a Symposium on "Peak Experiences in Psychotherapy" led by George R. Bach, Ph.D. and Nathan Cooper, M.A. Recently elected officers of the Chapter include Arthur H. Davidson, Ph.D., Chairman, Arthur Burton, Ph.D., Chairman-Elect and Verda Heisler, Ph.D., Secretary-Treasurer. For further information concerning the Chapter, write to Verda Heisler, Ph.D., 2306 Sixth Avenue, San Diego 1, California.

EAST BAY PSYCHIATRIC ASSOCIATION.

—The officers of this society for the year 1960 are as follows: Dr. Dora Fishback, President, Berkeley, Calif.; Dr. Allen S. Mariner, President-elect, San Leandro, Calif.; Dr. Richard E. Turk, Secretary, Berkeley,

Calif.; Dr. Robert K. Adamson, Treasurer, Berkeley, Calif.

Elected Councillor is: Dr. Anita U. Brothers, Berkeley, Calif.

THE NATIONAL HEALTH COUNCIL.—Granville W. Larimore, M. D., Deputy Commissioner of the New York State Department of Health, has been appointed Chairman of the 1961 National Health Forum, which represents more than 70 member agencies.

The 1961 Forum will be held at the Waldorf Astoria Hotel in New York City, March 13-16, 1961. The general subject for consideration: "Health and Communication." For information address The National Health Council, 1790 Broadway, New York 19, N. Y.

TEMPLE UNIVERSITY RESEARCH ON INSANITY AND THE LAW.—A grant of \$192,165 from the National Institute of Mental Health has been allotted to the Temple University Unit in Law and Psychiatry, and goes specifically to Dr. Samuel Polsky, associate professor of law, and Dr. Melvin S. Heller, assistant professor of psychiatry, co-directors of the Unit, for a three-year research program and study in "Insanity Procedures under Federal Law."

Under the terms of the grant, Drs. Heller and Polsky will make a joint legal and psychiatric study of the actual factors in the determination of competency to stand trial and criminal responsibility under Federal law.

ILLINOIS PSYCHIATRIC SOCIETY.—On April 20, 1960, the following members of the Illinois Psychiatric Society were elected for the year 1960-61, all of Chicago: President, Dr. Joel S. Handler; President-Elect, Dr. Melvin Shabshin; Secretary-Treasurer, Dr. Harold M. Visotsky; Councilors: Dr. Frances Hannett, Dr. Jackson A. Smith. Delegate to APA Assembly, Dr. Paul E. Nielson; Alternate Delegate, Dr. Jewett Goldsmith.

MUSIC REHABILITATION CENTER, NEW YORK CITY.—This rehabilitation service, established one year ago by the Musician's Emergency Fund in Carnegie Hall, has now moved to larger quarters at 50 W. 57th St.

This was to accommodate the increasing number of persons referred by clinics and by private psychiatrists.

The Center gives instrumental and vocal instruction as therapy to adult outpatients in liaison with the referring physician.

For information address Miss Florence Tyson, Director, Music Rehabilitation Center, 745 Fifth Avenue, New York City. PLaza 1-0530.

WORLD CONGRESS OF PSYCHIATRY III.—The Planning Committee for the Third World Congress of Psychiatry have informed us that plans are proceeding satisfactorily. Program and other arrangements have now progressed to the point where it is expected that the second announcement will be in the hands of all psychiatrists by September next. This announcement will contain full details regarding registration, accommodation, presentation of papers, and other related matters.

Meanwhile, those who are interested in presenting papers at this important meeting should notify the General Secretary of the Congress prior to September 1, 1960. Abstracts in triplicate, in not more than 250 words, in one of the official languages of the Congress should reach the Congress office at the Allan Memorial Institute, 1025 Pine Avenue West, Montreal 2, Quebec, Canada, not later than December 1. Dr. C. A. Roberts is General Secretary of the Congress.

PSYCHIATRY AND THE GENERAL PRACTITIONER.—The Western Interstate Commission and the Western Council on Mental Health Training and Research, through a 3-year grant from the National Institute of Mental Health, has begun an annual series of four 10 week courses in the psychiatric aspects of medical practice for general practitioners and other physicians in communities remote from medical teaching centers. This program is designed to augment the psychiatric knowledge and skills of physicians in community practice.

Courses have been held in Billings, Montana; Laramie, Wyoming; Phoenix, Arizona; and Lebanon, Oregon. Eventually courses will be given in all of the 13 Western states.

Klaus Berblinger, M.D., chief of clinical services at the Langley-Porter Neuropsychiatric Institute, San Francisco, is director of training and Warren T. Vaughan, M.D., director, WICHE Mental Health Project, is liaison officer and coordinator.

DR. L. E. PENNINGTON.—The death of Dr. Pennington, a Life Fellow of the APA and a veteran of World War I, occurred May 17, 1960 at his home in Jackson, Miss. at the age of 70.

Dr. Pennington was a graduate of the College of Pharmacy and Medicine of Emory University, Atlanta, Ga. He had served as superintendent of several mental hospitals and was also the founder of the Pennington Sanitarium in South Bend, Indiana. He had been the clinical director of Terrell State Hospital, Terrell, Tex. Later he joined the staff of the Mississippi State Hospital. He was past president of the Baldwin Medical Society; and was clinical instructor in psychiatry at the Mississippi Medical Center, attending physician at the University Hospital and a member of staff of the Veterans Administration Hospital at the time of his death.

TEMPLE UNIVERSITY MEDICAL CENTER.—The opening of a new 23-bed open floor unit for the treatment of combined mental and physical ills is announced by Dr. O. Spurgeon English, Head of the Department of Psychiatry. Although geared primarily to psychotherapeutic techniques, adjunctive treatment in the new section will include the use of drugs and electroshock. Dr. Harold Winn has been named director of the new section.

SIZE OF AMERICAN FAMILIES.—The *AMA News* quotes U. S. Census report that the size of the average American family increased from 3.54 in 1950 to 3.66 in 1959. Southern families numbering 3.81 were larger than those in any other region in the United States.

FOREIGN MEDICAL GRADUATES.—Of 6,029 foreign doctors who took the examination set by the Educational Council to qualify them to practice in the United States, as reported by *AMA News*, 3,345 (55.5%)

passed (the qualifying mark was 70). Only 33.1% scored 75 or better.

THE EDWARD A. STRECKER AWARD.—The first annual Edward A. Strecker Memorial Award for "outstanding service in the field of psychiatric aftercare" was presented by Horizon House, Inc. at its eighth annual community meeting May 18, 1960. Dr. Margaret Mead, cultural anthropologist, was the principal speaker at the meeting.

Judge David L. Ullman, a director of Horizon House presented the Memorial Medal to Walter A. Munns, president of Smith Kline & French Laboratories for the active support by the Philadelphia pharmaceutical house in cooperation with state mental health authorities throughout the country of after-care programs for released mental patients. Many patients have been enabled through these services to avoid a return to the hospital, and sizable savings for the state have also resulted.

Horizon House was established in 1953. It is a non-profit center which provides social rehabilitation, individual counseling and vocational services. A psychiatrically-trained professional staff is available to the patients at all times.

Dr. Strecker was for many years head of the department of psychiatry at the University of Pennsylvania, and was one of the first directors of Horizon House.

THE INTERNATIONAL SOCIETY OF THE PSYCHOPATHOLOGY OF EXPRESSION.—The second International Congress on Psychopathological Art will take place October 7-10, 1960 in Catania, Sicily. Manuscripts for presentation at this Congress must be submitted before July 15 to Dr. Gattuso, University of Catania, Sicily. Papers will be edited in the four official languages of the Congress, French, Italian, English and German. Paintings and drawings for the Exposition of Psychological Art associated with the meeting must be sent before August 31, 1960 to the same address. Those who intend to participate may register by writing to Prof. C. Pero, University of Catania, Sicily. The President of the Society is: Professor agr. R. Volmat, Centre Psychiatrique Sainte-Anne, 1 Rue Cabanis, Paris 14, France.

BOOK REVIEWS

CURRENT TRENDS IN THE DESCRIPTION AND ANALYSIS OF BEHAVIOR. Edited by Robert A. Patton. (Pittsburgh : University of Pittsburgh Press, 1958, pp. 242. \$4.00.)

This book is the ninth in the Current Trends in Psychology Series. Like its predecessors, it contains a series of papers delivered at the University of Pittsburgh, under the auspices of the Department of Psychology. The unifying theme which was supposed to bind the papers together was one of measurement, "since there is the continuous need for the development of methods to quantify the stubborn and elusive phenomena of behavior." The title of the book even suggests that this theme, like behavior itself, is too elusive to serve as the matrix for the gallimaufry of topics presented; only a few of the papers describe quantitative methods.

Without a unifying theme to serve as the focus of critical comment, it becomes necessary to review the series of papers independently.

I found the first two articles, by Robert Glaser and by Joseph Zubin, of particular interest. Glaser's paper, "Descriptive Variables for the Study of Task-Oriented Groups," describes quantitative sociometric methods for analyzing the behavior of small groups, particularly a task-oriented group such as a gunnery team. His method is ingenious and can have wider applications to "social process" as well as "task" variables. Zubin's paper, "A Biometric Model for Psychopathology," is a critique of present-day conceptual models designed for the understanding of psychopathology. He feels that we are still in a pre-Newtonian era, "Abnormal psychology is waiting for its Newton to provide new integrating concepts." Zubin sets up a possibly useful paradigm involving various levels of observed behavior *i.e.*, conceptual, psychomotor, perceptual, sensory, and physiological. Analysis of behavior can be accomplished by comparing the responses at the various levels at the idling state and with various stimuli, inappropriate, appropriate, configural, *etc.* He feels that with this technique "the patient population can be diagnosed more objectively, prognostic indicators of outcome promulgated, and the most suitable therapy for each type of patient determined."

In "Psychophysiology and Perception," Donald B. Lindsley discusses the impact of new

information regarding the ascending reticular activating system upon psychology. The effect of ARAS upon discrimination, perception, motivation, and selective attention and its role in the elaboration and integration of sensory messages is discussed in a very lucid way. He makes a plea for a fuller knowledge of the central nervous system functions as a significant factor "in the formulation of problems and the design of experiments in psychology."

Vincent Nowlis, in his paper, "On the Use of Drugs in the Analysis of Complex Human Behavior with Emphasis on the Study of Mood," describes some unusual methodological gambits in which he uses drugs to "control or systematically change factors relevant to basic psychological problems." He uses drugs to study psychology, rather than psychology to study drugs, though the two cannot be altogether separated.

Roy M. Hamlin's paper, "Scientific Methodology in the Area of Psychotherapy," is rambling and discursive, although he makes some excellent criticisms of the theoretical indoctrination inherent in psychoanalytic training as it is customarily conducted. He quotes Glover as saying that "the psychoanalytic training procedure is that of a self-reinforcing system with tremendous internal resistances to change." No one can disagree with Hamlin's feeling that we ought to "analyze and evaluate psychotherapy in a thorough-going, scientific fashion." A lot of people have been saying that for years, but only now are a few doing something about it.

HAROLD I. LIEF, M.D.,
New Orleans, La.

GROWTH AND DEVELOPMENT OF CHILDREN.

By Ernest H. Watson and George H. Lowrey. 3rd ed. (Chicago : Yearbook Publishers, Inc. 1958, pp. 334. \$7.75.)

The first edition of this work was published in 1952, the second in 1954, and the appearance of a third edition in 1958 indicates that this compact book has established a permanent place for itself. Indeed, the book has become the *vade mecum* of students and pediatricians preparing for the examinations of the American Board of Pediatrics. It is an excellent book, crammed with the most useful information, most readably set out, and easily assimilated by the reader. Every aspect of the growth and development of the child is cov-

ered, and the chapter devoted to the growth and development of "Behavior and Personality" is as full of useful facts and normative standards as the rest of the book, but in certain places it suffers from an unexpected fuzziness. We are told that "The ego has been defined as the seat of consciousness, and it controls voluntary actions." Such an archaism is surely going to be the reverse of helpful to the reader. There is no evidence anywhere in this chapter that Freud ever lived and wrote. Surely Freud's view of ego development was worth half-a-dozen lines?

There is a great deal more evidence available on the effects of prenatal influences on the physical development of the organism than the authors appear to be inclined to believe, and the physiology of adolescent development would have benefited from definitions which are more in keeping with the physiological facts. At this late date one surely would expect some discussion of the phenomenon of adolescent sterility from the physical, psychological, and social viewpoints. But these are the comments of a carping reviewer. The book is first-rate, abundantly supplied with the necessary tables, figures, and illustrations, references, and a good index. It will deservedly enjoy a long and useful life.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

PATHOLOGY OF TUMOURS OF THE NERVOUS SYSTEM. By Dorothy S. Russell, L. J. Rubinstein, and C. E. Lumsden. (London: Edward Arnold and Baltimore: The Williams and Wilkins Co., 1959, pp. 318, figs. 286. \$13.50.)

This companion volume to *Neuropathology* by Greenfield, Blackwood, McMenemey, Meyer and Norman, (1958), is welcomed as completing the modern British views in this important field of pathology.

The early chapters of the book are concerned with congenital tumours; meningiomas (with which primary sarcomata of meninges and brain are discussed); tumours of reticular tissue and tumours and hamartomas of blood-vessels.

The main chapter of the work, on primary tumours of neuro-ectodermal origin, accepts fully the view of anaplasia or de-differentiation in the production of gliomata of increasing malignancy, but does not accept the various methods, which have been advocated, of "grading" these tumours. The term's "malignant or anaplastic" astrocytoma and "glioblastoma multiforme" are, therefore, retained.

The medulloblastoma is considered to be essentially a cerebellar tumour. It is described among the gliomata, but its possible neuro-blastic origin is discussed.

The description of pineal neoplasms is important because of the authority with which the senior author writes.

An interesting discussion of the growth and dissemination of neuro-ectodermal tumors is followed by a chapter on the important subject of deformations of the brain produced by intracranial tumours. A chapter is devoted to secondary (metastatic) tumours.

Tumours of nerve-roots, peripheral nerves and peripheral neuronal tumours are well and fully discussed.

Finally, Professor Lumsden adds a chapter on tissue-culture of brain tumours, which is mainly a description of his results of "culturing" 39 tumours of varying histological malignancy in the astrocytoma-glioblastoma group. It will be of interest to see how his interpretation of his observations tallies with that of other workers.

The format of the book is uniform with its companion volume, the illustrations are excellent and the index is adequate. It will be a valuable and comprehensive chart to all who sail the stormy seas of neoplasia of the nervous system.

ERIC A. LINELL, M.D.,
Toronto, Ont.

EPIDEMIOLOGY OF MENTAL DISORDER. Edited By Benjamin Pasamanick. (Washington, D. C.: Publication No. 69 of the American Association for the Advancement of Science, pp. 336, ill., 1959. \$6.50. [\$5.75 to members of A.A.A.S.])

The twelve papers composing this symposium were presented at the New York meeting of the American Association for the Advancement of Science, December 27-28, 1956.

The symposium was organized by the American Psychiatric Association to commemorate the centennial of the birth of Emil Kraepelin, and was cosponsored by the American Public Health Association.

In his preface Pasamanick states: "Kraepelin's greatest contribution to psychiatry was his construction of a rational and usable classification of mental diseases, the first step in the systematic investigation of the etiology of disease. It is painful to note that we have advanced little since his death and, indeed, in many areas of psychiatry have regressed to that prescientific level, the unsystematic statements of outstanding clinicians." And

he adds, "By some, categorization of disease states has been decried as unnecessary and even harmful."

The participants in this colloquium represent an extraordinarily wide range of investigation—psychiatry, psychology, sociology, public health, biostatistics, pediatrics, anthropology, genetics and medicine. Each paper is followed by a prepared discussion which contributes additional data.

The symposium was opened by Eugen Kahn's masterly Emil Kraepelin Memorial Lecture. Kahn gives not only the main features of Kraepelin's life and of his career in psychiatry but also a condensed history of psychiatry itself during the nineteenth century, to show the impact of Kraepelin's teaching and the progress his orderly classification made possible. He cites the enduring concepts of the manic-depressive states and dementia praecox which Kraepelin set up, and quotes Bleuler: "The whole idea of dementia praecox stems from Kraepelin . . . The cradle of the concept is the fifth edition of Kraepelin's *Psychiatry*, 1896." And Kahn adds: "The work of more than one generation of psychiatrists would not have been possible without Kraepelin's achievements . . . Thirty years after Kraepelin's death there is no doubt as regards the clinical validity of the most important part of his psychiatric work." Best of all, Kahn gives a portrait of Kraepelin as his students and colleagues knew him, and as only one who had worked with the master could do. •

In discussing the paper, A Survey of Mental Diseases in an Urban Population, by Pasamanick, Roberts, Lemkau and Krueger, Diethelm paid further tribute to Kraepelin. He spoke of his "contributions of great value [among which] are his diagnostic classifications which have withstood the test of time." Noting that Kraepelin had been trained in experimental psychology under Wundt, Diethelm recalls that it was he "who brought an experimental basis to psychopathology versus a merely descriptive basis." He continues: "Kraepelin was the first one, so far as I know, who introduced an interdisciplinary approach . . . placing representatives of various disciplines on the same level . . . I think that we psychiatrists should be modest and see where our place is when we work with other disciplines."

Epidemiological studies are especially difficult and time consuming and liable to hazardous deductions, and the report by Pasamanick, *et al.* of their survey in the Baltimore area exemplifies caution in drawing conclusions. Referring to the exaggeration of other recent surveys that reported "approximately

two-thirds of the population being mentally ill," these observers concluded that their own finding that "approximately one-tenth of an urban population have one or more of the relatively well-defined mental disorders is sufficiently alarming."

In a study of personality change during adolescence based on test methods, Mangus and Dager examined 384 school children at the end of their first decade of life, with retest at the end of their second decade of life while in the upper grades of high school.

The results showed "that 14.1% of the subjects changed significantly upwards in their personality test scores while 8.6% moved downward to significantly lower levels of mental health. These rates and directions of change were about the same regardless of sex, age, or IQ of the subjects."

Significant factors in these changes were found to be such events as "have important impacts on the subject's conception of himself."

Considering the epidemiological aspects of prognosis, Zubin and Burdock quote from a study by Kraepelin written in 1894 in which he forecast the possibility by means of psychological tests of detecting individual deviations, "especially of the inborn pathological disposition . . . which cannot be recognized by ordinary observation." The detection of such deviations throws light on both predisposition and prognosis. Zubin and his associates remind us that it was Kraepelin "who introduced prognosis and follow-up studies into psychiatry" by means of "longitudinal" studies of many individual patients. His *tour de force* of "diagnosis by outcome" enabled him "to disentangle the nondeteriorating from the deteriorating psychoses, and in the latter he was able to distinguish the course of organic deterioration from that of functional deterioration. Such accomplishments loom large when compared with the confusion which preceded Kraepelin."

The authors note that epidemiological studies in mental disorders are still in a very early stage of development and have been mainly concerned with etiology. But in view of the importance of environmental factors not only in causation but also in rehabilitation the need for wider epidemiological research directed to the outcome of psychiatric disabilities is obvious. Some of the specific problems of epidemiological prognosis are discussed and attention is called to the wide gap that still exists between the achievements of epidemiology in the field of physical disease and its contributions in mental disease.

It would be of interest to review all the studies reported in this book but space limits us to brief and more or less random references. It is a valuable symposium, carrying forward leads that Kraepelin opened many years ago, and by bringing together representative contemporary views and results of recent studies emphasizes the role of epidemiology in psychiatric research.

C. B. F.

PSYCHOLOGY AND RELIGION: WEST AND EAST, VOL. 11. By C. G. Jung. (New York: Pantheon Books Inc., 1958, pp. 608. \$6.00.)

This volume of collected works of Dr. Jung contains writings on Western and Eastern religions from the years 1928 through 1954. Dr. Jung's basic considerations here are with Western religions and in this volume there appears the first translation of *A Psychological Approach to the Dogma of the Trinity*.

Present day psychiatry has seen the trend toward cooperation and a better understanding between religion and psychiatry. There have been sections at the American Psychiatric meetings devoted to this topic. The Academy of Religion and Mental Health is a strong union of clergy and doctors, sitting down in an effort to understand the work of the other more clearly. Dr. Jung's masterful writings here assembled under one cover are stimulating, provocative, and I am sure in some quarters and to some individuals would be considered controversial. However one may be oriented as to religion and to the kind of psychiatric therapeutic procedures and theories followed, the material in this book would be of immense interest and definite value to everyone in psychiatry, its allied fields and religion.

There is a greater detail of concern with the religions of the West than the East. Dr. Jung makes some deductions and conclusions as to the loss of symbolism in Protestantism and the psychological strengths embodied in some of the rituals of the Catholic Church. His discussion of the dogma of the Trinity and the Assumption of Mary is coherent and challenging.

A recent Broadway production, entitled "J.B." has stirred the imagination of theologians and psychologists and there are wide variations in the attempts to explain what the author of the play meant to convey. A national magazine carried articles by 3 leading clergymen of the 3 major faiths on their own ideas about what "J.B." meant. However, Jung, in a brilliant composition entitled "An-

swer to Job," which was first written in 1952, seems to get at the heart of the matter and really scoops the learned press and our friends in the clergy. He presents a profound and interesting evolution of what was the answer to Job, God's decision to learn from Job's experience and morality, to become a man and appear as Son of God, Christ.

Dr. Jung points out that the object of mutual concern is the psychically sick and suffering human being who is in need of consideration as much from the somatic or biological standpoint as from the spiritual or religious. This work should strengthen the goals of better understanding between the two major fields of religion and psychiatry. With each re-reading the essays shed new light. Some might find the tone of Jung's comments rather dogmatic or authoritative; however, the basic impact is of stimulation, not offense, and it becomes a very worthwhile and meaningful experience that would well be shared by our fellow readers. The comments about the reign of the anti-Christ will be of specific interest, I am sure, to theologians. I would dare say that through this collection of writings one also carries away a very strong impression of the extent and depth of understanding that Dr. Jung has of the writings in the Bible and other material of history prior to the record of the Bible, and each point is buttressed by many cross references, many examples, with copious footnotes, the bibliography alone exceeding 27 pages.

Psychology and religion, west and east, will gain by the publication of works such as this by Dr. C. G. Jung.

R. B. DEITCHMAN, M.D.,
Saint Louis, Mo.

SOCIOLOGY TODAY, PROBLEMS AND PROSPECTS. Edited by Robert K. Merton, Leonard Broom, and Leonard S. Cottrell. (New York: Basic Books, Inc., pp. 623 including index, 1959. \$7.50.)

Sociology Today is in more than one sense a monumental work. It is a large book—in format and in bulk. It embraces a series of 25 sociological expositions. Robert K. Merton writes the Introduction, Notes on Problem-Finding in Sociology.

The subtitle, "Problems and Prospects," in effect, and even as the editors affirm, but loosely, and I would add, inadequately, describes the nature and the scope of the texts presented. They embrace a good deal of historical and background data, provide much information on current works in sociology, and

sketch in judicious and critical terms the prevailing trends and countertrends in sociological thought, theory, and philosophy.

Sociology Today is neither a textbook nor yet a work to be read "from cover to cover"—save possibly by the academic sociologist who must cover the field entire. Of the 25 essays included in the volume, 2 (and also the Introduction) deal with Problems in Sociological Theory and Methodology. Eight are devoted to Problems in the Sociology of Institutions. Among the "institutions" treated are, politics, law, education, religion, the family, art, science, and medicine. Among these Bernard Barber's *The Sociology of Science* is likely to prove of particular interest to the psychiatrist and medical educator. Three essays deal with *The Group and the Person*, and 7 with Problems in Demographic and Social Structures. Five essays deal with Selected Applications of Sociology. Among these, John A. Clausen's *The Sociology of Mental Illness*, and Criminological Research by Marshall B. Clinard—are particularly pertinent to the psychiatrists' concerns.

This volume is, all in all, a first class work. It is also singularly free of the "jargonese" that is all too common in sociological texts.

IAGO GALDSTON, M.D.,
Academy of Medicine,
New York City.

THEORY OF PSYCHOANALYTIC TECHNIQUE. By Karl A. Menninger. (New York: Basic Books, Inc., 1958, pp. 206. \$4.75.)

It is now almost 30 years since Karl Menninger wrote a perennial best seller in the field of dynamic psychiatry, *The Human Mind*. It was followed by such works as *Man Against Himself*, *Love Against Hate*, various technical volumes and hundreds of scientific papers and addresses. Now he has addressed himself to a subject generally avoided by even the most prolific psychoanalytic writers.

The preface opens with a most appropriate quotation from Fenichel: "It is amazing how small a proportion of the very extensive psychoanalytic literature is devoted to psychoanalytic technique and how much less to the theory of technique." The current volume is, in the author's words, "about theory—the theory of therapy. It is not a manual of practice, but an examination of some of the psychodynamic principles operative in the practice." This is an accurate statement and answers in advance those who would find it, despite its

excellence, not encyclopaedic in content and scope.

This is no do-it-yourself handbook of psychoanalysis. It is an earnest statement of one eminent psychoanalytic scholar's concept of the theory of treatment, based upon years of assiduous study, practice and teaching. Clarified through constant exposure to the corrective comments of the keen minds of perceptive colleagues, his observations and formulations furnish a rich and rewarding field for study to the serious student of psychoanalysis.

The organization of the book is relatively simple, focusing on: (a) the psychoanalytic treatment situation as a two-party transaction or contract; (b) the regression which regularly occurs, discussed in terms of the reaction of the patient to the treatment situation; (c) transference and countertransference considered as in involuntary participation of the therapist in the treatment process; (d) resistance described in terms of the many paradoxical tendencies exhibited by the patient toward defeating the purpose of the therapeutic contract; (e) interpretation and other interventions discussed in terms of voluntary participation of the therapist, and (f) termination of the contract, the separation of the patient and therapist, which remains an unsolved riddle of analytic theory.

The book is well-written; significant writers' opinions are clearly expressed and the text is filled with apt and enlightening quotations, so characteristic of the author's style.

Many of the quotations as well as the author's opinions will probably prove surprising, both to those psychoanalytic practitioners who consider themselves orthodox in their methods and to those whose acceptance or understanding of psychoanalytic practice is skeptical at best. For example, quoting Freud: "I consider it quite justifiable to resort to more convenient methods of healing as long as there is any prospect of attaining anything by their means." This would seem to suggest that were Freud in practice today, he would certainly prefer the judicious use of electroshock treatment for severe depressions, rather than months or years of analysis.

In discussing the necessity for a certain attitude or frame of mind on the part of the psychoanalyst towards his task in the psychoanalytic situation, Menninger comments on the difficulty the average young doctor has to restrain himself from doing or saying something while the patient is struggling through the various steps of self-discovery. Menninger adds: "This restraint is very hard for the

average young doctor, particularly for the psychiatrist, to exercise—with the exception of those constitutionally passive individuals who seem to operate on the theory that healing rays emanate from them so that patients should get well by virtue of merely being exposed to those benign influences."

In discussing the fact that symptoms have no single cause but are over-determined, he quotes Tolstoy: "The combination of causes of phenomena is beyond the grasp of the human intellect. But the impulse to seek causes is innate in the soul of man."

Again in discussing the problem of not allowing contacts with the patient's family and friends to contaminate the treatment situation, the author states: "It seems to me absurd to stand on the principle that one has nothing to say to anyone but the patient. My impression is that it is often out of laziness, or lack of self-confidence, that many analysts refuse to see close relatives, thereby handicapping their efforts with the patient." In the opinion of the reviewer, the author would have done well to delineate this further, in terms of anxiety in the therapist whose degree of unconscious identification with the patient is such that to face relatives whom the patient feels are aligned against him is more than the therapist can bear—hence his position of rationalized, self-righteous isolation.

The author utilizes various schemata and paradigms, and in the case of interpretations and interventions some diagrams. In such an important schema as "Steps in the Regression," no mention is made of those instances where classic passivity is inadequate in initiating the regressive phenomena which the author (correctly, I feel) identifies as an integral part of the treatment process.

In a different sense, the author's interesting section "The Detection and Correction of Countertransference" seems most realistic and apt. Here he lists some common ways in which countertransference makes its appearance. This statement is appealingly candid, because, in the author's words, "I think that I have myself been guilty of practically all of them."

This relatively small volume has much to recommend it to the serious student of psychoanalysis, combining as it does humility, avoidance of cant, seriousness of purpose, and ideals common to the finest traditions of medical practice.

ROBERT T. MORSE, M.D.,
Washington, D. C.

THE SOCIETY OF CAPTIVES. By Gresham M. Sykes. (Princeton, N. J.: Princeton University Press, 1958, pp. 144. \$3.75.)

It has become axiomatic that no one lives in a vacuum, and this is particularly true in discussing socio-psychological problems. The felon has been the subject of many psychiatric and psychological studies, but the social matrix in which the convicted felon endures requires a discerning scrutiny. Psychiatrists recognize that there is a social system in the prison. Nevertheless, the "power politics" of this institution have perhaps not been so carefully examined. The present volume undertakes that examination in a serious, compact, well-thought-through study.

Professor Sykes regards the prison as a society within a society. In this way, he contrasts the implicit totalitarian regime of the custodians and its conflict with the democratic and individual-minded prisoners, as they seek to adjust to a rigid environment ordained by the larger society. Rules for order in prison life, ideas of punishment, the almost impossible task of the prisoner to adapt himself to an impossibly rigid life, the hierarchy of values among prisoners, the agents of prisoners—the "rat," center man, bully, good prisoner, the pervert—are all described and treated by the author.

The accent in this volume is not on psychopathic or emotional problems of the inmate, but on the total social structure of the prison, and of the guards. The guard, part of the totalitarian system of control, cannot escape a kind of fraternization with his prisoners; the prisoner, apparently devoted to anti-social attitudes, cannot escape absorbing some of the bureaucratic attitudes. Thus, a tight, rigid symbiosis develops within the society of captives, which has various repercussions and psychological reflections. All in all, it is the system that imposes restrictions on the man under control. It is the system that deprives the prisoner of autonomy in his daily movements, of sexual and emotional outlets. The pathology that arises in prison—homosexuality, brutality among inmates, thievery, fighting for preference, and even attempts at restitution on the part of good prisoners for cohesiveness among the prisoners, are all functions of the system. The pathology of prison life is more social than psycho-pathology. Although the author recognizes emotional instability on the part of individual inmates as determinative of some behavior, his accent is on the social system.

This orientation was further used in relation to prison riots, which the author describes as

a series of crises that make toward eventual equilibrium. He shows how riots occur when the balances within the prison system are interrupted, although the emergence of aggressive personalities into positions of leadership is also an effective force.

This slim volume by Professor Sykes is an impartial study of the prison as a social system. As such, it is objective, cleanly written and informed, and touches on vital problems within a maximum security prison set-up. Workers in penal institutions, including psychiatrists who may over-emphasize individual differences among felons in captivity, would benefit from Professor Sykes' re-emphasis on social forces existing between custodians and inmates. For without a view of the total "power" picture in the prison, one may get a biased view of the individual which might prejudice efforts at social and psychological rehabilitation of the inmate.

PROBLEMS OF ADDICTION AND HABITUATION.

Edited by *Paul H. Hoch, M.D.*, and *Joseph Zubin, Ph.D.* (New York* and London : Grune & Stratton, 1958, pp. 250. \$6.50.)

Since this book covers the proceedings of the Forty-Seventh Annual Meeting of the American Psychopathological Association, held in New York in February, 1957, it deals with many different subjects and presents many controversial hypotheses. Many of the papers contain new material and opinions that would be helpful and interesting, for both the psychiatrist and other physicians.

Some of the papers highlight little known facts concerning addiction in a manner that would be particularly useful for the practising physician. From this standpoint, the chapter "Withdrawal Convulsions and Withdrawal Psychoses" by Lothar B. Kalinowski, M.D., of the New York State Psychiatric Institute deserves special mention.

The study of Etiology of Pica in young children as an early pattern of addiction is interesting and, in my opinion, should be included in the overall subject of addiction. In his paper, "Some Problems of Addiction," Dr. Karl M. Bowman has summarized the general problem of addiction in a masterly fashion. Although Dr. Bowman has discussed the problem of addiction to alcohol, sedatives, narcotics, stimulants, tobacco and food, he did not stress sufficiently the problem of addiction to tranquillizing drugs, in particular, meprobamate, (Equanil and Miltown). It is now recognized by many that addiction to meprobamate can

produce withdrawal convulsions and withdrawal psychoses as severe as those referred to in Dr. Kalinowski's paper. The authors of Chapter 12, "The Role of Self-Image with Respect to Craving for Alcohol" attempt to uphold a thesis that could not be supported by many physicians who have been actively engaged in the treatment and rehabilitation of the alcohol addict.

The late Dr. Lester H. Gliedman of The Johns Hopkins Hospital, Baltimore, outlined an interesting study on group therapy in the treatment of chronic alcoholism. However, the effectiveness of this chapter is somewhat impaired by Dr. Gliedman's own admission of the disappointing results of his own experience with this method. To achieve good results, a group instruction and therapy plan may need to be carried on for 1 to 2 years and success improves with clinical experience.

The commentaries by Doctors Kramer and Lasagna and Freyhan and Zwerling, constitute a very effective spotlight for the book as a whole. In my opinion, their thought-provoking analyses of the subject matter of the book is an important part of the whole publication and assists the reader in orienting quickly to the parts of the book of special interest to him.

It should be noted that this book contains a directory of the membership of The American Psychopathological Association which, of itself, would be of interest and value to many people.

This is one of the better new publications dealing with the problems of addiction and habituation. It contains the opinions of eminent authorities in the field of psychopathology and would be a valuable addition to the library of the clinician who is in any way concerned with the problem of addiction.

The Bell Clinic, Willowdale, Ont.

PROGRESS IN NEUROLOGY AND PSYCHIATRY : AN ANNUAL REVIEW, VOL. 13. Edited by *E. A. Spiegel, M.D.* (New York : Grune and Stratton, 1958, pp. 611. \$12.00.)

This book which is published annually, reviews some 4,000 papers in the fields of Neurology and Psychiatry. It is divided into 4 sections : Neurology, Neurosurgery, Psychiatry and Basic Sciences. The scope of each section is broad, e.g., in the section on Psychiatry are the following chapters : Clinical Psychiatry ; Mental Hygiene ; Forensic Psychiatry ; Criminal Psychopathology ; Child Psychiatry ; The Neuroses ; Alcoholism ; Psychosomatic Medicine ; Psychoanalysis ; Psychological Assessment Techniques ; Group Psychotherapy ; Shock

Treatment; Psychopharmacology; Psychiatric Nursing and Occupational Therapy and Rehabilitation. Leading experts in each field review critically the significant contributions of the year. In all there are 63 authors.

Kline, in the chapter on Psychopharmacology, in view of the rapid developments in this field, gives an example of the optimistic view of some workers by quoting Gunsberg of South Africa: "I feel that in the future, within the next 25 to 50 years, as new developments take place, we shall require fewer beds for inpatients, and I am confident that the time is not far off when the present problem of overcrowding of mental hospitals will be a thing of the past, not because sufficient hospitals will have been built, but because of the present developments in therapy."

The range of subjects and the detail dealt with affords the reader with a survey of current advances and opinions. The extensive bibliography will be most useful.

The book maintains its high standards as a comprehensive annual review of the pertinent literature by recognized authorities.

JOHN G. DEWAN, M.D.,
Toronto, Canada.

CREATIVE ACTIVITY AND THE CREATIVE PERSONALITY (in Polish). By *Maria Naksanowicz-Golaszewska*. (Poland: Catholic U. of Lublin, 1958, pp. 329.)

This first volume of a proposed larger work covers only the subject of creative activity and its product. The book is a philosophic treatise, highly abstract, and not easy to follow for one accustomed to the less abstruse symbolism of medical literature.

The author defines creative activity as a specific psychophysiologic process within one individual giving rise to an original objective product. Creative activity results from a happy constellation of many factors such as emotional and intellectual tendencies and interests, the individual's conception of his ego, and the degree of determination or will. The creative process is subjective, its product objective. Both are interdependent and react upon each other until the product is finished when it leads a separate existence and exerts influence upon other personalities. To be creative, a product must be new and original, *i.e.*, unique, must have meaning for others and more or less permanent value.

The creative process has 2 phases, psychic experience and realization. Deep psychic experience alone, such as love, is not creative though it may motivate creative effort. Day dreaming and fantasies which are flights into

the paracosmos, are an antithesis of creativity which is the most intense kind of action.

The creative process begins with a concept which gradually attains form and substance. There is no regularity in the rhythm of creativity, some works being consummated in fleeting moments, others requiring decades. The beginning and the end of the creative process are difficult to define, for a "finished" product may be but a step to future productivity. Acquisition of mechanical skills and collection of data without a creative concept, in themselves cannot lead to a creative product. The concept and its objective synthetic externalization constitute the essential heterogeneous character of creativity. When the inner experience begins to be translated into external reality, doubt creeps into the situation and may cause the concept to die within the individual. Here enters the factor of will, *i.e.*, determination to make use of one's abilities, to sacrifice other equally attractive interests, to select from the environment elements favorable to one's project, to reject others, and to resist illusions and prejudices tending to modify the goal to be achieved. The author believes that a measure of free choice must be assumed as being indispensable for creative action. Moreover, she stresses the doctrine of the individual creator against the theory of precursors and co-creators. She believes that a created product worthy of the name, is always the work of one individual. Even when a person bases his work upon an idea of another, the latter is not a creator for he failed to attain the phase of realization. The author distinguishes 4 spheres of creative action: artistic, scientific, technical, and methodological—each envisaging a different aspect of man's contact with reality.

Her emphasis upon the individual in the genesis of creative works is in contrast to the current sociologic and anthropologic theories which depreciate the individual and regard creativity as little more than a reflection of the culture of the period. She also disagrees with those who assert that unfavorable circumstances thwart creative ability. If they do, she states, then the individual lacks true talent or strength or both. These unorthodox and debatable views are interesting, coming as they do from an area of the world where the official social philosophy has been conformity of individual thinking and acting to the higher dictates and direction of the state. To us in the U. S. A. they should serve as a reminder that fruitful creative action is not necessarily measured by the size and wealth of the research institutions.

TREATMENT OF SCHIZOPHRENIC REACTIONS WITH PHENOTHIAZINE DERIVATIVES

A Comparative Study of Chlorpromazine, Trifluorpromazine, Mepazine, Prochlorperazine, Perphenazine, and Phenobarbital¹

JESSE F. CASEY, M.D.,² JULIAN J. LASKY, Ph.D.,
C. JAMES KLETT, Ph.D.,³ AND LEO E. HOLLISTER, M.D.⁴

Since chlorpromazine⁵ has been proved useful in treating chronic hospitalized schizophrenics (1, 2, 3, 4), newer phenothiazine derivatives have appeared with claims of higher potency, greater therapeutic effectiveness, and fewer side effects or compli-

cations. After reviewing the voluminous literature, the harried clinician might still wonder whether any of the newer compounds were superior in any way. The reports on mepazine, for example, have ranged from enthusiastic endorsement to unqualified rejection (5, 6, 7, 8, 9): Bowes concluded that mepazine was twice as strong as, interchangeable and synergistic with chlorpromazine; Denber's sober title, "Ineffectiveness of mepazine . . ." completed the spectrum of opinion.

Recently more definitive studies of the newer phenothiazine derivatives have appeared (10, 11). Although these studies still contain contradictions, the differences are more understandable. In Freyhan's study of 10 phenothiazine compounds and reserpine, chlorpromazine was more effective than mepazine, reserpine, and promazine. It is inferred from his data that perphenazine, prochlorperazine, trifluoperazine and trifluorpromazine were not more effective than chlorpromazine, although he makes it clear that they caused more extrapyramidal reactions. Goldman differed with Freyhan, stating that perphenazine, prochlorperazine, and trifluorpromazine were more effective than chlorpromazine, caused fewer side effects and practically no complications. He could not differentiate therapeutically between perphenazine and prochlorperazine but found that trifluorpromazine produced fewer side effects than either. Some of these contradictions appear to be due to the use of different dosage schedules, criteria of improvement, treatment goals, and population samples.

With this and its own experience as a background (12, 13), the Veterans Administration began, in May 1958, a large-scale cooperative study of the relative therapeutic

¹ Project 3 of the Veterans Administration Cooperative Studies of Chemotherapy in Psychiatry. Preliminary results were presented at the Fourth Annual Research Conference on Chemotherapy in Psychiatry, VA Hospital, Memphis, Tenn., May 20, 1959. The indicated authorship connotes roles in planning or coordinating the study and preparing this report. Others who made major contributions were: T. G. Andrews, Ph.D., J. L. Bennett, M.D., E. M. Caffey, Jr., M.D., H. M. Houtchens, Ph.D., C. J. Lindley, M.A., M. Lorr, Ph.D., A. S. Marrazzi, M.D., A. Pokorney, M.D., and M. Rosenblum, M.D. The 35 VA hospitals which participated in this study are located at: Albany, N. Y., American Lake, Wash., Ann Arbor, Mich., Augusta, Ga., Battle Creek, Mich., Bay Pines, Fla., Biloxi, Miss., Brockton, Mass., Bronx, N. Y., Buffalo, N. Y., Coatesville, Pa., Danville, Ill., Denver, Colo., Downey, Ill., Fort Meade, S. Dak., Houston, Tex., Jefferson Barracks, Mo., Los Angeles, Calif., Lyons, N. J., Montrose, N. Y., Murfreesboro, Tenn., New York, N. Y., Northampton, Mass., North Little Rock, Ark., Northport, N. Y., Palo Alto, Calif., Perry Point, Md., Roseburg, Ore., Salt Lake City, Utah, Sepulveda, Calif., Togus, Me., Tomah, Wis., Topeka, Kan., Tuskegee, Ala., and Waco, Tex. Without the generous cooperation of staff personnel from these hospitals, this study would not have been possible.

⁴ Chief, Medical Service, VA Hospital, Palo Alto, Calif.

⁵ The generic and trade names of the drugs used in this study are: chlorpromazine—Thorazine (donated by Smith, Kline and French Laboratories), mepazine—Pacatal (Warner-Chilcott Laboratories), perphenazine—Trilafon (Schering Corporation), prochlorperazine—Compazine (Smith Kline and French), trifluorpromazine—Vesprin (E. R. Squibb and Sons).

effectiveness and toxicity of chlorpromazine, triflupromazine, mepazine, prochlorperazine, and perphenazine. Phenobarbital was used as a control medication.

PROCEDURE⁶

Patient Sample : Six hundred forty newly admitted schizophrenic men were studied in 35 VA hospitals. The average patient was 34 years old (the median was also 34), and the range was 18-54 years. He weighed 161 pounds, had finished 10% grades, had been a semi-skilled worker, and was first treated for mental illness 7½ years before his current admission. About half the patients were single, 30% were married, and the rest were divorced (10%) or separated (8%). The number of previous hospitalizations were as follows: none-18%, one-23%, two or three-27%, four or five-21%, six or more-11%. Forty-four percent had never received tranquilizers previously. All were in good physical health.

As measured by the Multidimensional Scale for Rating Psychiatric Patients-MSRPP(14), the average study patient before treatment was a little sicker, in general, but as active and no more depressed than the general population of schizophrenic men hospitalized in VA hospitals. He was somewhat more resistive, belligerent, withdrawn, and conceptually disorganized than the usual hospitalized schizophrenic veteran and markedly more paranoid, self-depreciatory, mentally agitated, active, and perceptually confused.

The attrition in the sample by the end of the study was 26%. One hundred fifty patients were dropped from the study. An additional 18 could not be included because of incomplete data. During the study period 85 patients left the hospital: 43 without medical approval, 24 on trial visits, and 18 by approved discharge. Also eliminated were 23 patients who were worse or had shown no improvement, 16 who refused medication, 4 who became seriously depressed, and 1 who was transferred. Finally,

21 patients were dropped; 12 because of side effects and 9 due to deviant laboratory findings.

Drugs, Dosage, Duration of Treatment: Identical-appearing coded medications were supplied to the hospitals from a central point in the following strength capsules: chlorpromazine, 50 and 200 mg.; triflupromazine and mepazine, 25 and 50 mg.; prochlorperazine, 10 and 25 mg.; perphenazine, 8, and 16 mg.; phenobarbital, 32 mg. These doses were chosen as equivalent on the basis of the manufacturer's recommendations. During the first 4 weeks of treatment, a fixed progressive dosage schedule was followed in all treatment groups: day 1; one low strength capsule; day 2, two low strength; day 3, three low strength; day 4, one high strength; days 5 through 14, two high strength; days 15 through 28, three high strength. During the remaining 8 weeks of the study, a flexible schedule was used in which the physician adjusted the dose, within limits of 1 to 6 high strength capsules daily, to produce optimal therapeutic effects in his individual patients.

Figure 1 shows the average number of capsules prescribed per week during the fifth through the twelfth weeks for patients in each of the 6 treatment groups. The average daily dose of each drug during the flexible dosage period was as follows: chlorpromazine, 635 mg.; triflupromazine, 175 mg.; mepazine, 190 mg.; prochlorperazine, 90 mg.; and perphenazine, 50 mg.

After the fifth week there were reliable variations among the treatment groups in number of capsules prescribed. Fewer capsules were prescribed for chlorpromazine patients than for any other group during the sixth week. In the eighth week and for the remainder of the study, significantly fewer capsules were prescribed for chlorpromazine and perphenazine patients than for mepazine or phenobarbital patients. Physicians used the full range of 1 to 6 capsules daily for each medication.

METHODS OF EVALUATING TREATMENT

Clinical Status: Clinical changes in patients were measured by two rating de-

⁶ The study protocol, reproduced in its entirety in the Transactions of the Third Annual Research Conference in Chemotherapy in Psychiatry, contains considerable detail concerning selection of patients, the randomization procedures, precautions, restrictions, laboratory controls and forms.

⁷ All differences discussed are statistically significant at or beyond the .05 level.

Average Weekly Dose of Capsules During the Flexible Dosage Period.

FIGURE 1

vices: the MSRPP and the Clinical Estimate of Psychiatric Status scale-CEPS(15). The MSRPP consists of two parts, the clinical interview section completed by a 2- or 3-man team of psychologists and psychiatrists, and a ward behavior section based on the observations of a 2- or 3-person team of nurses and nursing assistants. The MSRPP yields a total morbidity score which is an overall index of psychopathology and 11 additional scores which represent symptom clusters. The reliability of the MSRPP was estimated by having each member of the clinical and ward teams make their pre-treatment judgments independently before arriving at team consensus evaluations(16). The CEPS required judgments from psychiatrists on 12 items of psychopathology and prognosis. Patients were evaluated by both rating devices before and after 4 and 12 weeks of treatment.

Untoward Symptoms: The presence or absence of 18 specific symptoms and signs were checked and recorded weekly by the

physician. These included adverse behavioral effects, disturbances of the central and autonomic nervous systems and allergic reactions, chosen on the basis of known side effects of the phenothiazines.

Laboratory Measures: Hematologic tests included differential and total leucocyte counts obtained just before treatment and each week during treatment. Serum glutamic oxalacetic-transaminase (SGO-T) or serum alkaline phosphatase determinations were used as screening hepatic tests. Either of these tests was requested before treatment and then weekly for the first 5 weeks. If either was abnormal, a battery of additional hepatic tests was to be ordered. Pulse rate and blood pressure were recorded daily for the first weeks of treatment and morning temperatures were recorded daily for the first 8 weeks.

STATISTICAL ANALYSIS

The statistical model for evaluating the relative therapeutic effectiveness of the

study drugs was analysis of multiple covariance (simple randomized design). Each of the 24 criterion measures derived from the MSRPP and CEPS was analyzed for relative changes in clinical status during the first 4 weeks, the following 8 weeks, and over the entire 12-week study period. Final criterion mean scores in each analysis were adjusted for initial status on the criterion being analyzed as well as for the net effect of 11 control variables: age, education, occupational level, marital status, number of previous hospitalizations, nature of onset of first and current illness, months since condition first required medical attention, initial weight, history of previous tranquilizers and morbidity. In addition to adjusting the criterion means of the 6 treatment groups for whatever differences existed prior to treatment despite random assignment, this technique statistically eliminated that portion of the variability of the criterion associated with the covariates. The net effect of the adjustment was to provide statistical equality of the treatment groups

prior to treatment and to reduce the error term used in evaluating mean differences.

One thousand and eighty comparisons were carried out; each of 6 treatment groups being compared with each other, yielding 15 comparisons for each of 24 criteria over each of three time periods. The effect of making so many comparisons is to increase the likelihood of deciding there is a significant difference when in fact there is not. The findings were subjected to a multiple range test(17, 18) for protection against this kind of error.

RESULTS

Criteria of Clinical Effectiveness: Adjusted mean morbidity scores (MSRPP) for each of the 6 treatment groups are shown in Figure 2. The pretreatment mean is based upon the entire sample of patients. Even at the end of 4 weeks of treatment, a significant reduction in total morbidity had been produced by chlorpromazine, triflupromazine, prochlorperazine, and perphenazine as compared with phenobarbital. The differ-

EVALUATION PERIOD
FIGURE 2

ence between mepazine and phenobarbital was not significant at this time. When 12 weeks of treatment had been completed, all 5 phenothiazines had reduced morbidity significantly more than phenobarbital. Four of the phenothiazines were superior to mepazine at both the 4th and 12th week evaluations. There were no significant differences among the 4 more effective drugs. Even though the differences shown in Figure 2 between prochlorperazine and triflupromazine may appear to approach significance, this difference has a *p* value $> .20$.

The results of the analyses of relative change in the remaining 23 criteria of clinical effectiveness have been organized in Table 1 to emphasize the 3 main findings which occurred during two time periods.⁸

⁸ Detailed statistical tables containing the adjusted means, *F* ratios, and results of the multiple range test for all criteria at the three evaluation periods may be found as a supplement in the Appendix of the Transactions of the Fourth Annual

1. All five phenothiazine derivatives were therapeutically effective, i.e., they were superior to phenobarbital, the control drug, in respect to some important criteria of improvement. There were no instances in which the phenobarbital group showed reliably greater improvement than the phenothiazine groups. The ways in which all phenothiazines were superior to phenobarbital are shown in the upper portion of Table 1.

2. One of the phenothiazine derivatives was less effective than the other four. In every instance that mepazine surpassed phenobarbital, all other phenothiazines also did so. In the middle portion of Table 1 are listed those criteria of clinical effectiveness on which all phenothiazines except mepazine exceeded phenobarbital. In the lower third of Figure 1 are presented those cri-

Research Conference on Chemotherapy in Psychiatry. Inquiries concerning additional statistical or procedural details may be directed to the Central NP Research Laboratory, Perry Point, Md.

TABLE 1

CLINICAL DIFFERENCES BETWEEN VARIOUS PHENOTHIAZINE DERIVATIVES AND PHENOBARBITAL OR MEPAZINE IN NEWLY ADMITTED SCHIZOPHRENIC MEN

Patients receiving chlorpromazine, mepazine, perphenazine, prochlorperazine and triflupromazine were more improved than those receiving phenobarbital in the following ways:

After 4 Weeks

Less: resistive; belligerent; thinking disturbance; nursing care required.

After 12 Weeks

Same gains as after 4 weeks plus: less likely to injure others; greater chance for early discharge; greater chance for independence and self-support following discharge; illness less severe; condition improving; decrease in symptoms.

Patients receiving chlorpromazine, perphenazine, prochlorperazine and triflupromazine were noted more improved than those receiving phenobarbital in the following additional ways:

After 4 Weeks

Less: motor disturbance; likely to injure self. Decrease in symptoms, illness less severe, condition improving.

After 12 Weeks

Less: motor disturbance; likely to injure self; paranoid projection; perceptual distortion; AWOL potential. More participation in activities.

Patients receiving chlorpromazine, perphenazine, prochlorperazine and triflupromazine were more improved than those receiving mepazine as follows:

After 4 Weeks

Less: paranoid projection; motor disturbance.

After 12 Weeks

Less: motor disturbance; perceptual distortion; belligerence; thinking disturbance; likely to injure others; melancholy agitation. Decreased symptoms and greater chance for discharge. Condition improving.

teria with respect to which chlorpromazine, trifluorpromazine, prochlorperazine, and perphenazine were better than mepazine. There were no instances in which any of these phenothiazines was reliably worse than mepazine.

3. *The remaining four phenothiazine derivatives were not differentiated from one another in therapeutic effectiveness.* Over the entire 3-month period there were no significant differences among these 4 treatment groups on any of the 24 criteria.

SIDE EFFECTS AND LABORATORY FINDINGS

Only 21 patients (3%) were discontinued from treatment because of side reactions or deviant laboratory tests, this number being fairly evenly distributed among the 6 treatment groups. Five patients were dropped because of leucopenia. Four had deviant hepatic tests. Other reasons for termination included: 3 cases of Parkinsonism, 1 epigastric pain, 1 photophobia, 1 dermatitis, 2 deviant temperature or blood pressure, and 4 patients who became pale, nauseated, weak or hypotensive.

A detailed report of the abnormal symptoms, signs and laboratory tests has been published elsewhere(19). The piperazinyl-phenothiazines, perphenazine and prochlorperazine, produced most of the side effects followed by the aliphatic phenothiazines, chlorpromazine and trifluorpromazine. Mepazine and phenobarbital produced the fewest side effects. Although the extrapyramidal syndrome was unique for the phenothiazines (and most pronounced with the piperazinyl derivatives), most of the other side effects measured, including adverse behavioral reactions and autonomic nervous system effects, were also reported in some measure for phenobarbital. Hematologic changes (leucopenia, eosinophilia, and leucocytosis) were encountered with all drugs without significant differences in frequency. The same was true of abnormal hepatic tests, none of the patients having a definite clinical picture of jaundice.

DISCUSSION

Since this study was designed as a comparative evaluation of 4 newer phenothiazines with chlorpromazine serving as a standard or reference treatment, emphasis

was placed upon the *relative* effectiveness and toxicity of these 5 agents rather than the evaluation of any one considered independently. Phenobarbital, mimicking some of the properties of the phenothiazines, was included as an active placebo. To be considered an effective agent, any phenothiazine derivative should be superior, at least, to a conventional sedative.

The fact that all the phenothiazines studied were effective in reducing some aspects of psychopathology is evident from their comparison with phenobarbital and is consistent with most published reports. Of greater interest are the symptoms affected. After one month of treatment with these drugs, patients were less resistive, belligerent, and disturbed in their thinking than patients receiving phenobarbital. These changes were accompanied by a decrease in the amount of physical nursing care required. Further gains were made during the last two months of the study. Psychiatric judgments indicated that patients receiving the phenothiazine derivatives had better prospects for early discharge and were more likely to be independent and self-supporting after discharge than patients receiving phenobarbital.

In short, any of the 5 phenothiazine derivatives produced clinical effects superior to phenobarbital. It is inferred that these 5 agents would be superior to an inert placebo group or to a group that had received no capsules at all. The reduction in morbidity of the phenobarbital group during treatment was slight and did not reach significance. A previous VA cooperative study based on a large sample of chronic schizophrenic patients demonstrated that neither a placebo nor phenobarbital had therapeutic value nor was either more effective than the other(1).

Although all the phenothiazines were more effective than phenobarbital, mepazine was less effective than the other four. This finding may be related to differences in chemical structure as discussed by Himwich(20). One explanation of mepazine's apparent inferiority might be that it had been used at too low a dose. During most of the first month of treatment, mepazine patients received 150 mgs./day, the lower limit of the range of maximal therapeutic

effectiveness as defined by Feldman(21). The largest amount a patient in this study could receive during the flexible dosage period was 300 mgs./day, the upper limit of Feldman's range. That 150 mgs./day was not optimal is clearly demonstrated by the increments in mean dosage of mepazine shown in Figure 1. Although the mean daily dose of mepazine given to patients during the flexible dosage period was 190 mgs., in the final weeks of the study, approximately a third of these patients were receiving the maximum amount allowed by the study protocol (300 mgs.) and side effects were minimal. In the light of current knowledge, it may be assumed that the unit dose of mepazine used in this study should have been approximately that of chlorpromazine.

The interpretation of the finding that the 4 remaining phenothiazines did not differ significantly is not an obvious one. Statistical logic does not permit the conclusion that these compounds are identical in action. Interpretation must be guided by the experimental conditions which produced the results. The purpose of random assignment of patients to treatment, the double blind procedure and statistical adjustment for initial differences was to prevent one treatment group from having an advantage over any other except in terms of the treatment being evaluated. The flexible dosage schedule was chosen to allow each drug to be evaluated at approximately optimal dosage. The choice of criteria of clinical effectiveness was intended to encompass a large portion of the domain of psychopathology. The reliability of the MSRPP was investigated and considered satisfactory. However, some may feel that such measures are either too insensitive to capture the subtle nuances of drug differences or have missed important areas of behavioral change. Within the limitations of this design, the findings are consistent and are considered reliable.

The high dropout rate (168 patients, 26%) in this study raised two questions. First, was there any evidence of selective dropout related to treatment group? In terms of total number of dropouts in each treatment group from all causes, there were no significant differences between the

groups. However, a disproportionate number of patients on triflupromazine were out of the hospital (26 of a total of 85) prior to the end of the treatment period. It is difficult to evaluate this as a biasing factor, in that 16 of these patients left against medical advice or without permission, which may not necessarily relate to the results of treatment. A disproportionate number of patients on phenobarbital and mepazine (16 of a total of 23) were dropped because of lack of improvement or worsening of their condition. This situation was consistent with the clinical findings and did not constitute a source of obscuring bias. Second, were these patients different in any way from those completing the study? Patients who left the hospital prior to the end of the study for whatever reason were in general not as ill initially as those remaining until the end of the study. Patients leaving without medical approval, the greatest number of whom were in the triflupromazine group, had lower morbidity scores, were less depressed and withdrawn and showed less disturbance in thinking before treatment than did those who remained in treatment for the entire period.

When this study was conceived, the controlled evaluation of side reactions and abnormal laboratory results during therapy with phenothiazine drugs was considered potentially more important than therapeutic differences between the drugs. In some respects this prediction was true, though not in the manner thought. The most outstanding finding was the comparative paucity of severe abnormalities, accounting for only a 3% loss in the total sample. Next in interest was the lack of difference in prevalence of abnormal symptoms, signs, and laboratory tests between the phenothiazines and, surprisingly, phenobarbital. In the case of phenobarbital, these abnormalities included such adverse behavioral effects as depression or agitation, autonomic effects such as blurred vision or dry mucous membranes, such presumed central nervous effects as akathisia, as well as eosinophilia, leucocytosis, leucopenia and abnormal hepatic tests. In many instances, these abnormalities probably represented manifestations of schizophrenia or spontaneous fluctuations completely unrelated to drug

therapy. The failure to encounter any instance of frank jaundice or agranulocytosis in 530 patients treated with phenothiazine derivatives suggests that these complications may have been more feared in the past than was warranted. In view of the frequent abnormalities associated with phenobarbital therapy, especially those not commonly attributed to this drug before, one must be cautious in ascribing all that happens during drug therapy to the drugs being used. The original intent to discover some index between therapeutic effectiveness of the drugs and side reactions or laboratory abnormalities was not feasible with so little difference between the agents in either regard.

Although this study offers considerable information regarding the clinical effectiveness, side effects, and toxicity of 5 phenothiazines used under the described conditions, the data necessary to guide drug therapy of individual schizophrenic patients are not provided. With the data from this and other studies and his personal experience with drugs as background material, the physician must still select a specific drug for an individual patient, taking into consideration such factors as speed of action; dosage schedules; treatment goals; combinations, potentiation, and sequences of drugs; duration of effects; calculated risks and safety; convenience; cost; subjective patient response; compatibility with other treatments; and any special features or unique advantages of a given drug.

SUMMARY

Six hundred forty newly-admitted schizophrenic men in 35 VA hospitals were randomly assigned to chlorpromazine, triflupromazine, mepazine, prochlorperazine, perphenazine and phenobarbital groups. Treatment followed a double blind procedure for 12 weeks. Patients were started on low "equivalent" doses of each drug which were gradually increased in a predetermined manner during the first 4 weeks. During the final 8 weeks, each prescribing physician adjusted the dose for each of his patients in order to evoke an optimal therapeutic response.

Average daily doses during the flexible period were: chlorpromazine, 635 mg.;

triflupromazine, 175 mg.; mepazine, 190 mg.; prochlorperazine, 90 mg.; and perphenazine, 50 mg. Clinical evaluations using two rating scales provided 24 criteria of change. For each criterion, the mean of each of the 6 treatment groups adjusted for the net effect of 12 control variables was compared by analysis of multiple covariance with the mean of every other treatment group at each of three evaluation periods; first month, the following 2 months, and over the entire 3 months. Side effects, hematologic and hepatic function data were also recorded during the course of treatment. One hundred sixty-eight patients failed to complete the study.

In general, the results indicated that all 5 phenothiazine derivatives were therapeutically more effective than phenobarbital. Mepazine was less effective than the other 4 drugs at the doses employed. No significant differences in therapeutic efficacy were noted between chlorpromazine, triflupromazine, prochlorperazine, and perphenazine. Criterion measures showing change toward improvement after treatment with phenothiazine derivatives included resistiveness, belligerence, thinking disturbance, and degree of illness. Other criteria affected favorably, especially by the 4 more potent phenothiazines, were motor disturbance, paranoid projection, perceptual distortion and withdrawal.

Only 21 patients (3%) were discontinued from treatment because of side reactions or deviant laboratory tests. Most side reactions, especially the extrapyramidal syndromes, were produced by perphenazine and prochlorperazine. Phenobarbital was associated with a number of side reactions ("turbulence," autonomic symptoms) commonly attributed only to the phenothiazine derivatives. Abnormal hematologic tests including eosinophilia, leucocytosis and leucopenia were neither frequent nor severe. The distribution of the 36 patients with leucopenia was not significantly different among the treatment groups. Continued treatment with the drugs in 31 leucopenic patients produced no case of agranulocytosis. Although abnormal hepatic tests occurred in 88 patients, these were sporadic. No clear-cut case of jaundice or hepatic dysfunction was encountered during treatment.

MODES OF ABSTRACT THINKING AND PSYCHOSIS

N. McCONAGHY, M.B., D.P.M.¹

Surprisingly little interest has been taken in recent decades by either psychiatrists or psychologists in the ways in which people think. Evidence of this is the present widespread rejection of the distinction between the schizophrenic and paranoid groups of psychoses, established by psychiatrists at the turn of the century on the basis of the difference they observed in the types of abstract thought found in these two conditions. The fact that this difference exists has never been denied, it is now not considered of sufficient importance to justify the distinction into two illnesses. However, in medicine when the aetiology of an illness is not known, it is considered a separate condition if a common symptomatology and prognosis is present. In this case, along with the difference in thinking between schizophrenia and paranoia there is also a difference in outcome. It therefore seems that a prejudice exists against considering intellectual processes as symptoms. This is further evidence of the influence of psycho-analytic thought on orthodox psychiatry, as within that frame-work it is impossible to consider modes of thinking as other than secondary to emotional disturbances. Freud (1) himself led the way in abandoning the distinction between these two conditions when he based his theory of paranoia on the autobiographical writings of a patient suffering from schizophrenia—"paranoid" schizophrenia (another lamentable instance of the confusion wrought in psychiatry by the use of adjectives in an entirely different sense from their nouns(2, 3). This disinterest has again been demonstrated in the neglect of Bleuler's brilliant description(4) of the mode of thinking which he termed a "loosening of the associational structure" and which he considered the primary symptom of schizophrenia. This valuable finding is rendered meaningless if the paranoid group of psychoses are included as a sub-group of schizophrenia, when as Bleuler emphasised,

they are characterised by an entirely different, one could say opposite, form of thinking.

Just as knowledge of the physiological and pathological disturbance of organs often throws light on their mode of function, so study of these variations in thinking may provide insight into its mechanism. Bleuler put forward such a theory, based on his findings on schizophrenic thought, which may well repay examination :

In analysing the disturbance of association, we must realise the influences which actually guide our thinking. Associations formed in terms of habit, similarity, subordination, causality, *etc.*, of course will never generate truly fertile thoughts. Only the goal-directed concept can weld the links of the associative chain into logical thought. (For example), the idea of water is quite different depending on whether it relates to chemistry, physiology, navigation, landscape, inundation or source of power. Each of these special ideas becomes connected with the other ideas by a quite different set of threads. No healthy person thinks of soda-water when his house is being swept away by a flood ; nor will he think of water as a medium of transportation when he is thirsty . . . in the normal mind only those particular concepts dominate the picture that belong to a given frame of reference . . . the (schizophrenic) patients may lose themselves in the most irrelevant side-associations, and a uniform chain of thought does not come about. . . . (Schizophrenic) thinking operates with ideas and concepts which have no, or a completely insufficient, connection with the main idea and should be excluded from the thought-process. It is probable that in the normal psyche there are inhibitions which prevent the use of disparate associational material and hinder the transition to another theme. . . . The best known result of these tendencies is the "constriction of the field of conscious awareness"; that is the inability of healthy people to think of several different things simultaneously. . . . If these inhibitions can be overcome in the normal psyche, it is obvious they can fail completely in schizophrenics . . . (a) *lack of inhibition*. . . .

Thus, from his observations of schizophrenic thought, Bleuler independently ar-

¹ Senior Lecturer, University of Melbourne, Victoria, Australia, Department of Psychiatry, Royal Melbourne Hospital and Prince Henry Hospital.

rived at an identical theory of mental function as did Pavlov from his experiments with conditional reflexes in dogs, viz. that a mental act proceeded by the excitation of appropriate associations while the rest of the associations were placed under a state of inhibition. Pavlov(5) also found that dogs varied in "personality" according to the strength or weakness of these processes and considered human beings would show similar differences. That is, what Bleuler considered a symptom of schizophrenia—a weakness of inhibition—Pavlov found in some dogs as a permanent condition, producing a typical "personality." If we were to accept Pavlov's findings, we would put forward the hypothesis that the type of thinking found in schizophrenia is in fact one variety of normal thought and has been considered a symptom of schizophrenia because it occurs in most patients with this illness, often in a more marked form. This is actually the conclusion the author came to from observing the thought processes of both schizophrenics and normals. It was initially noticed that, as many schizophrenic patients improved, the grosser forms of thought disturbance such as the tendency to invent new words, or to be so disconnected in their thinking as to be unintelligible, disappeared. There was then left a characteristic type of abstract thinking. If a patient showing this form of thinking was encouraged to express ideas and form opinions rather than recount past experiences, there became obvious a certain vagueness or imprecision in his concept formation, so that his exact meaning was never clear. Also he would introduce new material the relevance of which was only partly, if at all, apparent. Of course this difference in type of thinking is quite subtle and at times is only apparent after some minutes' conversation, but it was shown by the majority of the author's patients diagnosed as suffering from schizophrenia, and rarely by patients with other conditions.

If the majority of mankind were colour-blind, persons without this defect would encounter great difficulty in persuading their fellows that objects could be distinguished by their colour. Observations in psychiatry are often so subjective that in

attempting to establish them, one feels placed in a somewhat similar position. The existence of a different type of thinking in otherwise normal people has been noticed previously by at least two psychiatrists and yet failed to be accepted. Bleuler said of the thought disorder he described, which is clearly identical with that noted by the author, that it persisted in cured or latent schizophrenics though it may require "patient and persistent observation to reveal it." Skottowe(6) described the thinking of many of his schizophrenic patients as showing what he called dys-symbols, which he defined as :

a state of mind which manifests itself by the inability of the patient to formulate his conceptual thoughts upon personal topics or to discriminate the gradations of his emotions in language which is intelligible to others, notwithstanding that he may be in a state of clear consciousness, while he still retains word utilizing ability at the level of perceptual thinking and is not aphasic in terms of sensorimotor neurology.

It is clear that the type of thought disorder described by Bleuler would produce this inability, though Skottowe may have noted it only in relation to the patient's thoughts on personal topics or his emotions, as these are generally the subjects discussed in a psychiatric interview. Skottowe emphasised that this disturbance in thinking always persisted in spite of treatment.

If this type of thinking in a schizophrenic patient never disappears, even though he may recover from the schizophrenic episode in all other respects, might it not have preceded the illness, in fact, have characterised the patient's thinking all his life? If so, one would expect to find a percentage of normal individuals showing this type of thinking who have never had a psychiatric illness. This is what the author has observed. As this type of thinking became a clearly defined entity, it was noticed that some of his acquaintances showed it as clearly as did the recovered schizophrenics.

Actually there was a precedent for this observation also. Rapaport(7) when investigating the value of his Object Sorting Test found that if he scored it so as to indicate the presence of "loose" associations in his subjects' thinking, schizophrenic pa-

tients scored highly, but so did a proportion of his normal control group, an indication that the type of thinking found in schizophrenic patients was also present in a percentage of normal individuals. This finding was followed up in a study by Lovibond and the author already partly reported (8), which utilised the model of thinking provided by Bleuler and Pavlov.

Using this model, one would postulate that irrelevant associations in thinking are due to a general weakness of inhibition affecting all associations and therefore that the concepts formed by a subject would show a constant degree of irrelevance irrespective of their content. Hence if a subject could be encouraged to form concepts whose degree of irrelevance could be measured, even though these concepts were completely unrelated to his personal or emotional problems, the measurement should correlate with the presence of this type of thinking observed in a clinical interview.

An Object Sorting Test provides concepts measurable in this way. In this type of test one asks the subject why various groups of objects belong together. The degree to which his answer applies to objects not included in the group provides a measure of its irrelevance. For instance, Rapaport's test utilises 33 objects commonly encountered in everyday experience. A series of groups selected from these are presented to the subject, each group implying an abstract-conceptual definition of the objects in it, such as "eating utensils," "smoking requisites," "red" objects. The subject is asked "Why do all these objects belong together?" The degree to which his answer includes objects not in the group presented is a measure of its irrelevance. A score of one may be given to definitions of belongingness which would include not only the test group, but half the remaining test material also (e.g. "They all burn"); a score of two to definitions which would include all the test material (e.g. "They all belong in a house"); and a score of three to definitions which would include practically all inanimate objects in the universe (e.g. "They all come out of the ground"). Utilising this modification of Rapaport's method of scoring, it was shown that a score of above 6 correlated significantly with the

presence of this type of thinking in schizophrenics and a score of 6 or less with its absence. Also it was shown that 10% of a control group of normals scored above 6. It is considered that this study provided objective evidence for the author's observation that a specific type of thinking, similar to that described by Bleuler and Skottowe, is found in a high percentage of schizophrenics and a smaller percentage of normals.

The question then arises, what determines the presence of this type of thinking in a particular individual, if it is not due to a schizophrenic illness? It has already been advanced that it is due to a weakness of inhibition at the level of what Pavlov termed the higher nervous activity. He considered such variations in the strength of excitation and inhibition in dogs were determined constitutionally. This is also the conclusion the author came to from observing the parents of patients and normals with this type of thinking. In all cases, at least one parent showed this type of thinking. To put this observation on a more objective basis the parents of schizophrenic patients with thought disorder were tested with the Object Sorting Test. In every case at least one obtained a score of above 6 on the test, indicating the presence of this type of thinking (9).

If one is to consider the hypothesis that this type of thinking is found in about 10% of normals and is inherited in dominant fashion, further problems must be considered. Firstly, why does it occur in a much higher percentage of patients diagnosed as suffering from schizophrenia? It is considered that it acts as, or indicates the presence of, a predisposition to this illness. Why then does this hereditary predisposition to a severe and often chronic illness affecting people early in the pre-creative period of their lives, not die out? One reason is that obviously only a small percentage of people who show this type of thinking actually develop schizophrenia.

In addition the author has been led to conclude that such thinking conveys advantages to its possessors since they so frequently demonstrate great ability in certain occupations. That it is particularly of value to artists is fairly obvious. People

who show it introduce into their thinking associations, the relevance or logic of which is only partially, if at all, immediately apparent to people without it. To choose a gross example, the ability to see people as birds or as other emotive or comical figures is plainly of great value to the cartoonist, and the schizophrenic nature of much verbal humour—the partial irrelevance and partial relevance of such a transposition as “the all leather Goon Show”—is widely recognised. A more subtle but no less real advantage is given to the serious visual artist—the ability to see in certain shapes relationships of emotional significance which the rest of us would reject preconsciously as not relevant until actually faced with them. The gifted writer who is prevented by this condition from being fully aware of the logical grounds on which people act, is sensitised to the emotional ones and can depict a world of people acting on strange impulses which is clearly of sufficient, even if partial, truth to provide a powerful experience for his readers: D. H. Lawrence is a perfect if a somewhat extreme example.

However, in the intellectual sphere there is also profit to be had from this type of thinking. The learning of entirely new modes of thinking—as in mathematics and electronics—is apparently made easier, to judge by the success in these fields of people with this type of thinking. The reality of $\sqrt{-1}$ or the acceptance that a particle can also be a wave must be less of a problem to people not restricted by inexorable logic. As well as its aid to creativity which can obviously apply only to a few, this condition also increases its possessor's ability to appreciate and profit by innovations of all sorts. These persons, therefore, encourage progress not only in the arts but also in business, and are often found making a success of what seemed initially a very odd idea. Probably their most obvious characteristic and perhaps their greatest attribute is their tendency in every-day life to be more sensitised to, and aware of, the emotional side of the behaviour of others, to be intuitive rather than deductive, and if this often leads them into falsity and exaggeration, inpeccable logic, for all its greater social acceptability, can do likewise. For it is considered by the author

that this in extreme form also exists as a special type of thinking which can equally distort reality yet equally throw light on certain of its aspects.

It was considered that the type of thinking already discussed was due to a weakness of inhibition. What would result if inhibition were extremely strong? Once a series of ideas were logically connected they would tend to inhibit the rest of the associations and so be less likely to be affected by implications to the contrary. The author has noted thinking of this sort in patients with paranoid forms of illness and again been led to notice the same thinking in normals.

When a paranoid patient informs you of his delusional beliefs, every nuance in the behaviour of others, every minor change in his environment, which would be dismissed as coincidental by others, but which can be logically related to his beliefs by the patient, is recounted in remorseless detail. One feels a growing irritation with this terribly prolonged account of unimportant incidents which, to the patient, are proof positive of his beliefs. If then one goes to a committee meeting one may feel the same sense of irritation as one of its members puts forward with unanswerable logic some prolonged argument such as that if a particular step is taken it may establish a precedent which may permit various undesirable consequences. Considerations of expediency are ignored by him and long after he realises he has lost the sympathy of the committee, he feels impelled by his conviction of the rectitude of his case to continue to argue it. A “bush-lawyer” is the local expression for such individuals. They inevitably feel resentful and misunderstood, unable to grasp why their perfectly argued case does not win universal acceptance. The author considers that here we are again dealing with an inherited type of thinking, predisposing the recipients to a paranoid psychosis. It is suggested that the delusions of persecution so common in this latter condition are a logical development from the constant reaction of annoyance such persons produce in others. That is, this type of thinking is the primary disturbance in paranoia, not unacceptable feelings of love, which are “reversed” into feelings of hatred

and "projected" on to the environment as was suggested by Freud(1). This type of thinking gives advantages to the possessor enabling him both to analyse events in detail and to build up logical theories to account for his observations. Of course these theories may end as vast superstructures on fairly slender foundations, but as they are internally consistent they are held with great tenacity by their author and often win wide acceptance. It would seem that Freudian theory is itself such a construction, and has often been criticised as such. Unfortunately this has not prevented some of its critics from developing equally substantial psychological theories on equally slight observations.

It is interesting to note the extent to which writers have been aware of these differences in people. The Broadway writers of comedy in particular have been fascinated by the scatter-brained, logically deficient woman and revelled in the triumph of her sound, though apparently "zany," intuitions over what seems to appear to them a hard-hearted and hard-headed society with no time for frivolity: "Auntie Mame" and "The Solid Gold Cadillac" being two examples. A more sensitive portrayal of a person with schizophrenic thinking is that of Mrs. Moore in E. M. Forster's *A Passage to India*. In this novel two of her children are depicted as sharing her intuitive, sensitive nature and rather incoherent speech, while the third child is a clear-thinking realist, an indication of the author's awareness of the familial nature of the condition. Perhaps the most brilliant exposition of the paranoid thinker is in *Othello*. The inability of the hero to reject his belief that Desdemona's loss of the handkerchief is proof of her infidelity once this idea is incorporated into his logical system is one of Shakespeare's many brilliant insights. In my experience with paranoid patients it has been paralleled again and again by the significance one has attached to the shifting of the fluid level in a bottle of poison, another to the crushed appearance of his wife's bed-covering, and so on. Once again the observations have been made by the artist long in advance of the psychiatrist.

In summary, it is suggested that all persons' thinking is not identical. Two extreme modes of thinking are described. In the first, the ability of the mind to exclude logically irrelevant associations is weakened so that thought processes are vaguer and more dominated by intuition. In the second, the ability of the mind to give a logical meaning to environmental events is strengthened, so that once such a meaning is found, it is held with greater tenacity, while opposing considerations have less influence, resulting in a triumph of logic over common-sense. Evidence is advanced that the first type of thinking affects about 10% of the population, acts as, or indicates the presence of, a predisposition to schizophrenia and is inherited in dominant fashion. It is the author's impression that the second type of thinking acts as a predisposition to paranoid psychoses and a possible mechanism is suggested. It is further suggested that these types of thinking could result respectively from a weak and a very strong process of inhibition in the higher nervous activity, to use Pavlov's theory of mental function.

SOCIOPSYCHOLOGICAL CHARACTERISTICS OF RESIDENT PSYCHIATRISTS AND THEIR USE OF DRUG THERAPY¹

GERALD L. KLERMAN, M.D.,² MYRON R. SHARAF, Ph.D.,³
MATHILDA HOLZMAN, M.A.,³ AND DANIEL J. LEVINSON, Ph.D.⁴

INTRODUCTION

Why do some psychiatrists prescribe drug therapy for their patients more than do others? The answers to this question form part of the larger problem of understanding the process of decision-making in psychiatric treatment. The factors involved in any treatment decision are many: the psychopathology being treated, social background of the patient, the treatment setting, the treatment goals, alternative treatments available, and the orientation and personality of the psychiatrist.* In recent years, excellent studies have clarified our understanding of a number of these factors. For example, Hollingshead and Redlich have demonstrated that the patient's social class is frequently a significant determinant of the form of psychiatric treatment he receives(1). Other studies have directed attention to the importance of the social characteristics of the treatment setting(2). It would appear, however, that even with similar patients and in comparable settings, psychiatrists differ in their propensity to utilize the currently available therapies.

There is now a small, but growing, literature on the personal feelings and values of the psychiatrist relating to his use of different therapies. Studies, mainly by psy-

chiatrists and social scientists, have shown that the more the psychiatrist is oriented towards psychotherapy and the greater is his commitment to a psychodynamic theoretical approach, the less likely he is to use the somatic therapies(3, 4, 5). Others, primarily psychoanalysts and dynamically-oriented psychiatrists, have suggested that in prescribing the somatic therapies, the psychiatrist is inappropriately applying the traditional medical role-model to psychiatry (6, 7, 8). In addition, irrational feelings, especially punitive motives and authoritarian trends, have been ascribed to the psychiatrist who prescribes these treatments.

While interpretations of this kind were originally applied to psychiatrists advocating psychosurgery and the shock therapies, they have recently been carried over to the users of the new psychopharmacologic agents. For example, Szasz, in discussing drug treatment, equates the tranquilizing drugs with restraint, regarding them as "chemical strait jackets"(8). He argues that they remove from the psychiatrist the guilt and remorse which served as moral safeguards when he used the older and cruder forms of physical restraint. Szasz further states that drug treatment benefits the family and others around the patient, rather than being, as is usually claimed, primarily for the patient's own welfare. This point of view is also shared by Meerloo who has compared drug therapy to "brainwashing"(9).

It is worth noting that these observers actually employ only one edge of the psychodynamic sword. They postulate irrational emotions on the part of psychiatrists who use drug therapy. However, these same motivational concepts could be applied to analyze the possible role of irrational factors in the non-use of drug therapy by other psychiatrists.

This is a study of the use of drug therapy in a teaching hospital where the psychia-

¹ Revision of a paper presented at the Divisional Meeting of the American Psychiatric Association, New York, Nov. 27, 1959. This investigation was supported in part by research grants M-687 and M-1000 from the National Institute of Mental Health, U. S. Public Health Service.

trists were found to differ considerably in their use of drug therapy. The aims of the study were: (a) to develop measures of the differential use of drug therapy by psychiatrists; (b) to determine the possible relationship between the psychiatrist's use of drug therapy and his personality characteristics, especially authoritarianism and related trends; and (c) to consider the possible ways in which irrational motives and feelings may be involved in low, as well as high, use of drug therapy.

RESEARCH SETTING AND PROCEDURE

The study was conducted on the adult inpatient services of the Massachusetts Mental Health Center (formerly, the Boston Psychopathic Hospital), a small state hospital affiliated with the Harvard Medical School. The hospital specializes in short-term intensive treatment and is also well known as a training and research center (10). Its daily inpatient census expanded during the period of this study from 120 to 170 patients. The admission rate varies between 600 and 900 patients a year. Over 85% of the admitted patients were discharged to the community, the remainder being transferred to other institutions. The mean duration of hospitalization was 8.2 weeks. The hospital treatment program emphasizes individual and group psychotherapy. More than half of the patients receive psychotherapy. The treatment of adult inpatients is carried on predominantly by the resident psychiatrists under the supervision of staff psychiatrists, many of whom are members of the Boston Psychoanalytic Society.

The study was carried out during a recent academic year, during which approximately 35% of all admissions received drug therapy, either briefly or intensively, often in conjunction with other treatments, usually psychotherapy. Of those who received drug therapy, approximately one-half were given drugs within the first week of hospitalization. The mean duration of drug prescription was 6.3 weeks.

Our sample consists of 12 resident psychiatrists in the first year of their training. They constitute the entire group of residents assigned to the inpatient adult services during the year of this study. Almost all the resident psychiatrists were interested

in learning psychodynamics and practicing psychotherapy, although they varied in the strength of their commitment to psychotherapy and in the range of their other professional interests(11). The residents were given a number of sociopsychological tests and were interviewed several times during the year regarding their hospital experiences and their attitudes toward various forms of treatment.

THE MEASUREMENT OF DRUG USAGE

As stated previously, 35% of the patients received drug therapy at some time during their hospitalization. While there are few published reports of rates of drug use in hospital settings(12, 13), it is our impression that this represents a moderate degree of drug usage. From the information available to us, both from the literature and from informal sources, the rate of drug therapy at this hospital appears to be lower than on the admission services of most public mental hospitals while higher than in private psychiatric hospitals or university training centers. The overall percentage of patients receiving drug therapy at this hospital has remained relatively stable in recent years. However, the individual psychiatrists have varied considerably in the extent to which they have prescribed drugs. Our first problem was to develop a valid index of a psychiatrist's use of drug therapy.

In developing this index, we were cognizant of the interaction between the individual psychiatrist's own inclinations and the influences, both overt and covert, upon him from the hospital milieu. The decision to prescribe drug therapy for a patient in the hospital setting is the result of complex social forces and group processes(14). In contrast to his colleagues in private practice, the hospital psychiatrist often has to accommodate his theoretical persuasions and treatment orientations to the hospital's administrative needs. In addition to the psychiatrist's preferences, the needs and wishes of other staff members influence treatment decisions. Frequently, when drugs are prescribed, the initiative in the prescription comes from staff members other than the psychiatrists. In these situations, drug therapy, prescribed for only short periods, is being used for the temporary relief of severe

symptoms, the management of intercurrent ward crises or the resolution of temporary impasses in psychotherapy. In these instances, drug therapy is an ancillary rather than primary treatment. While no index of drug usage can be completely independent of these milieu influences, we attempted to derive an index which would be a valid and sensitive measure of the psychiatrist's use of drug therapy as a sustained treatment procedure.

Information on the use of drugs was obtained by reviewing the hospital experience of all patients admitted during the period of study. We surveyed the case records and ward charts of all patients admitted to the hospital during an 11-month period from July 1 to the following June 1. For each patient admitted, we ascertained the resident psychiatrist responsible for his treatment and the duration, in weeks, of hospitalization. For those patients receiving drug therapy, we ascertained the interval between admission and the start of drug therapy, and its duration.

The index used as the measure of each psychiatrist's prescription of drug therapy denotes the percent of the total hospitalization time that his patients were receiving drug therapy. This index was obtained by dividing the number of weeks the resident's patients were on drugs by the total weeks all of his patients were hospitalized. This index was derived for each psychiatrist. The lowest index obtained was 15%, indicating that this psychiatrist's patients, taken as a group, received drug therapy during 15% of their total weeks of hospitalization. The highest value was 52%. The mean value for the group of 12 residents was 28%. This index was considered to reflect the resident's utilization of drug therapy as a sustained and enduring form of treatment.

We tested a number of different indices; for example, the percentage of patients a psychiatrist started on drug therapy during the first week of hospitalization, and the average duration of drug therapy. However, the index described above proved the most useful. It is beyond the scope of this paper to present the data on indices of drug use and the inter-correlations among the different indices. It is worth noting that

the indices differed in their correlations with the sociopsychological measures. The derivation of valid indices of drug usage remains an important research problem.

DRUG USAGE AND AUTHORITARIANISM

In the studies referred to earlier, various investigators hypothesized that the propensity to use drug therapy reflected aspects of the psychiatrist's authoritarianism. In our attempt to test this hypothesis, we employed the F Scale as a measure of authoritarianism (15). This scale contains a number of statements concerning authority, work, sex, aggression and human nature. Typical items are, "People can be divided into two distinct classes: the weak and the strong," and "Sex crimes, such as rape and attack on children, deserve more than mere imprisonment; such criminals ought to be whipped in public or worse." High scores have been shown to indicate a variety of authoritarian trends, including punitiveness and alienation from one's inner life. In recent years, this scale has been used in psychiatric settings and the scores of staff members have been found to relate to various aspects of hospital functioning (16). Furthermore, patients' F scores have been shown to be predictive of the type of treatment they receive; patients with higher F scores tend to receive ECT, while psychotherapy is more often given to patients with lower F scores (17, 18).

The scores on this scale have a possible range from 10 to 70 points with a midpoint of 40. The mean F score in our sample was 24; the range was 11 to 36. It is of special note that the highest F score did not reach the midpoint of the scale. Thus, as a group, the resident psychiatrists were strongly non-authoritarian. Their mean was very much lower, *i.e.* less authoritarian, than that of a sample of surgical residents (19), but comparable to the means found in previous studies of other psychiatrists in America (16) and in Britain (20). Within this restricted range, from very low to moderately low F scores, was there any relationship between authoritarianism and drug use? As shown in Table I, the F Scale scores did correlate highly with the index of drug use. The F Scale correlated 0.66 with the index of drug usage. This correlation indicated

TABLE 1

CORRELATIONS BETWEEN PSYCHIATRISTS' USE OF DRUG THERAPY
AND THEIR SCORES ON SOCIOPSYCHOLOGICAL MEASURES*

Index of Drug Use	Sociopsychological Measures			
	F Scale	S Cluster	C Cluster	A Cluster
Percentage of their total hospitalization time during which the psychiatrist's patients were on drug therapy	.66**	.60**	.60**	.51**

** Statistically significant. Critical values for sample size of twelve are 0.506 ($p = 0.05$) and 0.712 ($p = 0.01$).

that the higher a psychiatrist's score on the F Scale, the more likely were his patients to receive drug therapy during their hospitalization.

Further data bearing on the relationship of these personality trends to drug use were obtained from a newly developed Values Inventory (21), which was administered to the psychiatrists independently of the other tests. This Values Inventory contains 146 statements dealing with personal feelings and interpersonal relations. The statements are grouped into 8 clusters, 3 of which were found to relate to drug usage.

The S Cluster deals with issues of status and social hierarchies. A high score indicates high value on manifest status differences and on leader-follower relationships. An example is "There should be a definite hierarchy in an organization with definite duties for everyone."

The C Cluster deals with character and honor. A high score on this cluster indicates strong value on the exercise of strict self-control, the maintenance of honor, and a sense of duty. An item is "The higher type of person makes a sense of duty the groundwork of his character."

The A Cluster deals with assertiveness and aggression. A high score on this scale indicates strong value on dealing with problems in an active, outspoken, decisive fashion even if the feelings of others are hurt. An example is "I feel like criticizing someone publicly if he deserves it."

Few of the resident psychiatrists scored high on any of these three clusters; most of the scores were moderate to low. Thus, as

a group, they did not value the assertive behavior, hierarchical status differences or ideas of duty measured by these three clusters. However, the range of scores on these clusters was wider than on the F Scale. As shown in Table 1, these three Value Clusters correlated significantly with the index of drug usage. These correlations indicate that the psychiatrists who use drug therapy frequently tend to value assertive and decisive behavior more than their colleagues who use drug therapy to a lesser extent. They also place relatively greater value upon manifest status differences, sense of duty, and self-control than the psychiatrists who are low drug users.

DISCUSSION

Our findings can be briefly summarized. The sample of psychiatrists, as a group, show a limited range—from moderate to low—with regard to both their use of drugs and their scores on measures of authoritarianism and related values. Within this range, we found that, as their use of drug therapy increases, so also did the psychiatrists' scores on the F Scale and on the 3 related Values Clusters. Stated otherwise, we have evidence of 2 treatment-personality patterns: first, what we shall call the "low" pattern, psychiatrists with very low scores on drug usage and authoritarianism; and, second, the "middle" pattern, psychiatrists with moderate scores on both sets of measures.

Although our sample showed only this restricted range, a possible third pattern

should also be considered—the “high” pattern, psychiatrists with relatively high rates of drug use associated with high scores on measures of authoritarianism. We have the impression that this “high” pattern would rarely be seen in most residency training centers, but might be found in more diverse psychiatric settings.

How can we best understand these two patterns? Let us first consider the “middle” pattern. On the basis of their scores on the sociopsychological tests and information derived from participant observation and interviews, we have constructed the following summary of the treatment orientation and value preferences of the psychiatrists in the “middle” group.

The psychiatrists in this “middle” group, to a greater extent than their colleagues in the “low” group, value assertiveness, self-control, and forceful leadership. Holding these values, they are willing to assume a moderate degree of authority and to exercise their medical responsibility in treating and caring for their patients. They consider it their obligation as physicians to use every reasonable means to promote symptom-reduction, to relieve the patient's distress, and to maintain a relatively stable ward atmosphere. Their moderate, rather than low, rate of drug usage is consistent with this orientation.

To what extent are irrational feelings and motives involved in the behavior of these psychiatrists? The fact that they earned higher F scores than the “lows” might be interpreted as supporting the view expressed in the literature cited earlier; namely, that their propensity to use somatic treatments is a reflection of punitiveness and related authoritarian qualities. Their more traditional definition of their medical role, as the doctor who works on, rather than exclusively with, his patients, could be regarded as another expression of moderate authoritarian tendencies. It could also be hypothesized that their use of drugs is motivated not merely by a wish to help their patients, but also by some defensive need to control patients' impulsive or disturbed behavior which the psychiatrists themselves find threatening.

However, this interpretation is based upon two assumptions: first, that moderate

drug use in itself reflects the punitiveness, the defensiveness and the nondynamic approach to patient care alleged to be present in psychiatrists who use drugs and other somatic therapies to a great extent; and second, that their range of scores on the F Scale represents to only a lesser degree the same pattern of personality dynamics demonstrated for high F scorers (15). It can be argued, however, that neither of these assumptions is valid. It is possible that the psychiatrists in the “middle” pattern are using drugs flexibly and with consideration of their patients' varied needs; that is, in a nonpunitive and nondefensive manner. Similarly, their middle range of F scores may not represent only quantitatively less authoritarianism but rather may involve the operation of qualitatively different personality trends involving such features as the willingness to accept responsibility and the capacity to set limits on deviant behavior.

Let us now examine the “low” pattern in a similar manner. The “low” psychiatrists are more opposed than their “middle” colleagues to status hierarchies and to assertive behavior, especially when such behavior might be violating the feelings of others. Believing in these values, they prefer psychological treatments which maximize the patient's role as an active participant in his own treatment. The “low” psychiatrists see a conflict between the traditional medical role, with its emphasis of taking responsibility and active intervention, and their concept of the psychiatrist's role as primarily that of the psychotherapist. Their limited drug use is consistent with these values; values also expressed, explicitly or implicitly, in the writings of Szasz, Meerloo and others who are critical of the use of somatic therapies in psychiatry.

However, the same question can be asked of the psychiatrists in the “low” pattern as was previously asked of the “middle” pattern: To what extent are irrational feelings and motives involved in their attitudes and behavior? It may be argued that irrational forces are operating when they delay or avoid prescribing drug therapy for patients who might benefit thereby. From the results of previous studies of low F scores, it could also be inferred that the inhibition of aggression as well as strong identification with

the underdog may be features of their personalities. Psychiatrists with these tendencies may disapprove of drug therapy from an irrational fear that this would punish or limit their patients. Possibly, these tendencies reflect a confusion of authoritarianism with authoritativeness. The high value placed by them on psychological modes of treatment may also be accompanied by insecurity about their own psychotherapeutic skills. In this insecure position, they may perceive the use of drugs as an indication of the failure of their psychotherapeutic efforts. We observed that their aversion to acting in an assertive or directive manner was laden with emotion, indicating that this was an area of conflict for them. It may be that these concerns relate to their resistance to accepting the learning of techniques in drug therapy as a part of their psychiatric skills.

Thus, the findings of this study relating to the psychological meaning of the "low" and "middle" patterns of drug use can be interpreted in different ways. Further research may demonstrate that irrational forces play a larger role in the decision-making behavior of the psychiatrists committed to one of these two treatment orientations. However, our own feeling, as yet untested, is that neither group has a premium on rationality. Within both groups, there probably are wide differences in the degree to which treatment-decisions reflect defensive needs of the therapist rather than therapeutic needs of the patient.

Further research in this area should, we believe, include even more intensive clinical and interview material than we utilized in this study. It might be particularly fruitful to explore the clinical course of patients about whose treatment there were marked differences of professional opinion. In these situations, we would predict that the psychiatrists holding "low" pattern of values would limit their use of drugs more than would the psychiatrists who exemplify the "middle" pattern. The intensive investigation of these "problematic" instances would, we hypothesize, reveal that the "lows," in deciding against drug therapy, do so partly from the fear of being punitive or assertive, and that the "middles" in prescribing drugs are motivated partly by the wish to control

or punish anxiety-provoking behavior. In addition to specific personality vulnerabilities and characteristic therapeutic blind-spots, the two groups also have different types of professional assets and personal satisfactions. Thus, we predict that the "middles," more than the "lows," would experience the satisfaction of acting in an authoritative—but not necessarily punitive—manner when confronted with difficult clinical situations or ward management problems. Correspondingly, the "lows" more often would feel gratified in helping patients to master their conflicts and anxieties without the need of external controls such as drugs. Similar differences in sources of professional justification were found in a survey of psychiatric practitioners (4).

The question may well be asked: Of what value is it to know about feeling and motives of psychiatrists related to their choice of a particular treatment? It may be hypothesized that the greater the admixture of irrationality in the treatment decision, the less likely is the treatment to be effective. However, there is no simple relationship between the motives of the psychiatrist in prescribing a treatment and its subsequent efficacy. It is possible for a psychiatrist to reach the "right" decision for "wrong" reasons and the "wrong" decision for the "right" reasons. Moreover, the "right" and "wrong" of treatment decisions are difficult to establish. Wide differences of opinion currently exist among psychiatrists as to the indications for drug therapy and there are few criteria for determining when a particular drug prescription is appropriate or inappropriate. Nor are there standards for judging whether a psychiatrist's use of drug therapy is excessive or reasonable. The absence of such criteria contributes to the phillipics and unconstructive arguments that currently pass between the advocates of different psychiatric therapies. In these arguments, discussion and criticism too easily become polemics. The undesirable attributes of the extreme advocates of one treatment are ascribed to moderate users, which provokes the criticized psychiatrists to counter with attacks on their critics' motives and personalities.

We believe that the psychiatrist's personality is an important determinant of his

treatment decisions. As such, it is an important area for research, quite apart from the question of how much his personality accounts for the efficacy of drug treatment. Among other contributions, such research would help to clarify the nature of psychiatrists' resistance to using certain treatment methods.

However, the controversial nature of this subject requires that the investigator avoid polemics and be open-minded to the assets, as well as the liabilities, of psychiatrists specializing in different treatments. A broad sociopsychological framework is also necessary to deal with the interplay of individual personality and social processes. In spite of these difficulties, research on these problems would seem particularly relevant to the complex problems currently encountered in the mental health field. •

HAZARDS OF DRUG EVALUATION : TRIALS OF 84 NON-APPROVED DRUGS

JACKSON A. SMITH, M.D.,¹ AND CECIL L. WITTON, M.D.²

Neuropsychiatry, like other areas of medical practice, is fortunately faced with an increasing number of potentially beneficial new medications. The magnitude of this increase is shown by the 2,500 papers published between 1952 and 1957 on psychopharmacology(1).

Since the encouraging results observed during the testing of a new drug in animals cannot be routinely duplicated in the patient, the determination of the effectiveness of an untried medication ultimately depends on clinical evaluation. This report is based on the clinical evaluation of 84 drugs prior to their approval by the Food and Drug Administration.

In addition to the possible toxicity of unproven drugs, other formidable factors influence their clinical evaluation: 1. The geographic isolation of the institutions which house chronic patients from medical centers, 2. The lack of status of this type of research, 3. A lack of interest in drug treatment by psychiatrists in the "analytic-psychological" type of practice, and 4. The source of the new compounds to be tested.

TOXICITY OF THE DRUGS TESTED

Between July 1955 and July 1959, a total of 93 different drugs were evaluated in two Nebraska state hospitals and the Nebraska Psychiatric Institute.³ Of these, 84 had not yet been approved by the Food and Drug Administration. These 93 drugs were administered to 1,704 patients, approximately a quarter of whom participated in more than one study.

Two deaths occurred in these groups during the 4 years' study. One, a 67-year-old male, apparently suffered a coronary occlusion during a trial of a phenothiazine derivative; and the second, an 88-year-old female, died while receiving a cholesterol

lowering compound which she had tolerated previously without difficulty. Neither death was related to the drug, nor were similar incidents reported by other investigators using the same compound in similar types of patients.

Reversible side effects were frequently seen, particularly with the phenothiazine derivatives at higher doses. In these evaluations it was necessary to determine the therapeutic and toxic dose as well as whether the product was effective.

To assure close observation of the patients, research units, consisting of one or more psychiatric nurses, a technician and a secretary, were established in the state hospitals. These personnel had no service function, and their responsibility was entirely to the research department, which permitted close observation of the patients in the various projects. Any side effects observed were immediately reported to a staff physician in the institution. Routine laboratory studies were done each week.

It would appear from this experience with 93 drugs in 1,704 patients that if those receiving new medications are closely observed and the medical care is adequate, the testing of new drugs certainly does not entail undue hazards.

OTHER PROBLEMS IN DRUG EVALUATION

The isolation of chronic patients from medical centers: Those for whom more effective treatment is most needed are frequently located in medically and geographically isolated hospitals. They are also the patients who are most available for drug studies. On the other hand, university medical centers with their concentrations of research personnel are located in metropolitan areas; and little or no connection may exist between these medical centers and the state hospitals.

Lack of status of this type of research: Another difficulty that retards the clinical evaluation of drugs results from the nature of this sort of research. It is not a very inspirational type of endeavor. Essentially,

¹ Clinical Director, Illinois State Psychiatric Institute, Chicago, Ill.

² Director, Nebraska Psychiatric Institute, Omaha, Nebr.

³ Several of these projects were supported by a grant from the National Institutes of Mental Health.

the psychiatrist is merely testing someone else's ideas, and this is not in keeping with the concept that "senior investigators" hold of their function.

Drug research is made even less inspirational by the routine that repeated evaluation requires, and the need to prevent the contamination of the results by an investigator's enthusiasm. The lack of originality required in planning such efforts, the frequency of negative results, and the lower status of this type of research offer little motivation for clinical investigators.

Lack of interest in drug treatment and drug research in some types of psychiatric practice: One problem in doing drug research results from a peculiarity* of the present day practice of psychiatry. This problem was well illustrated in a study of patterns followed in neuropsychiatric practice by Maciver and Redlich(2).

These authors interviewed 40 psychiatrists and found that two rather distinct types of psychiatry were practiced in this country; one type was termed "analytic-psychological" the other "directive-organic." Those in the "analytic-psychological" group rely almost entirely on psychological and non-directive methods in their therapy. An emphasis on understanding the patient's thinking and his personality was seen as the goal of practice by the "analytic-psychological" group. This could ordinarily be accomplished without the benefit of drug therapy.

It was noted that all the university psychiatrists interviewed were in the "analytic-psychological" type of practice. When questioned about organic therapies those of this persuasion replied: "I've no experience with them," "I know little about them; I'm skeptical of the efficacy," and "They're used more than justified."

The other type of psychiatrist described as "directive-organic" in his orientation was much more enthusiastic about somatic methods of treatment. These psychiatrists were most rewarded by seeing the patient progress, relieving his symptoms and curing him. None of this group was a university psychiatrist.

The source of new compounds to be

tested: The production of medications for the treatment of the mentally ill, during the past few years, has enhanced the clinician's dependence on pharmaceutical firms for new compounds and information. This trend has disturbed both physicians and non-medical groups.

However, until medical schools or university research centers become the source of more effective compounds, the trend will probably continue and increase. The physician prescribing a medication seldom ponders whether the research biochemist, who originated the idea which lead to its development, was on the staff of a university or a pharmaceutical firm. His primary interest is in the effectiveness of the compound rather than the atmosphere in which it was conceived.

As disturbing as this trend to depend on the maker of the product for information may be, it would be much more disturbing if these research efforts to develop more effective compounds ceased. The dramatic, expensive and occasionally exaggerated advertisements which seek to inform and influence the clinician are perhaps of more value to the journal in which they appear than to the potential reader.

CONCLUSIONS

1. If sufficient medical care is provided, compounds on which adequate animal toxicity studies have been done, do not appear to involve hazards in clinical trials. This conclusion is based on 93 drugs evaluated over a 4-year period in 1,704 patients; 84 of these drugs had not been approved by the Food and Drug Administration.

2. Other factors which tend to delay drug evaluation efforts include: the isolation of the chronically mentally ill from medical research centers, the lack of status associated with this type of research, the peculiarities of psychiatric practice and the source of the new compounds available for evaluation.

THE RELATIONSHIP OF MENTAL AND PHYSICAL STATUS IN INSTITUTIONALIZED AGED PERSONS

R. L. KAHN, Ph.D., A. I. GOLDFARB, M.D.,
M. POLLACK, Ph.D., AND I. E. GERBER, M.D.¹

Large numbers of aged persons reside in homes for the aged, nursing homes, and psychiatric hospitals. Each type of institution ostensibly offers special services in response to specific needs. Thus, the old age home is considered to offer social aids, the nursing home medical assistance, and the mental hospital psychiatric care. This concept of specificity of service implies that the needs of the aged are also specific, that they can be categorized as chiefly in need of social, psychiatric, or general medical assistance.

The purpose of this report is to examine the validity of the concept of need specificity in regard to psychiatric and medical care. Data for this were made available by the direct examination of the mental and physical characteristics of a group of aged persons randomly selected from the 3 types of institutions. This population is part of a larger institutionalized group of aged persons studied and reported elsewhere⁽¹⁾.

METHOD

Population: Persons residing in nursing homes, homes for the aged and state mental hospitals located in New York City who were 65 years of age or over at the time of first admission to the institution, were sampled and examined within a 30-day period.²

¹ From the Office of the Consultant on Services for the Aged, New York State Department of Mental Hygiene, Queens Village, N. Y., Alvin I. Goldfarb, M.D., Consultant. This is an expanded version of the paper read at the Eleventh Annual Meeting of the Gerontological Society, Inc., Philadelphia, Pa., Nov. 6, 1958.

² The old age homes in New York City are non-profit institutions which are usually members of sectarian federations of social agencies. The State Department of Social Welfare supervises old age homes in New York City. The nursing homes are commercial institutions, licensed by the New York City Department of Hospitals, and the City Department of Welfare pays for the care of many persons in them. The state hospitals are public psychiatric hospitals for the care of the mentally ill maintained and administered by the state through the Department of Mental Hygiene.

The entire survey was completed in the period February–October, 1958.³

The institutions as well as the persons tested within each institution were selected by random sampling. The 3 state hospitals in New York City were sampled, with the total of 200 patients examined drawn entirely from those admitted within 2 years preceding the survey month. Four hundred twenty-five persons in 13 of the 102 proprietary nursing homes registered by the Department of Hospitals in January 3, 1956, and 506 persons in 9 of the 49 homes for the aged listed by the Community Council of New York City in 1957 were examined.

Procedure: Each subject was examined by a physician and tested by a psychologist. The mental and physical examinations were completed within 30 days of each other. The physician's examination and the brief medical history he obtained were used to evaluate the subject's physical functional status. This was categorized in terms of 3 grades of physical capacity as follows:⁴

Grade A. Unrestricted or moderately restricted physical capacity: individuals who can take care of their own needs or who may need a small or moderate amount of supervision and assistance. Persons with unrestricted physical capacity can live alone, travel alone, and take care of their home needs. Moderately restricted activity is often occasioned, for example, by heart failure or osteoarthritis which is severe but does not confine the patient to bed, poor eyesight, amputation, malnutrition, and debilitation in association with slow growing malignant neoplasms or blood dyscrasia.

Grade B. Restricted activity—marked: individuals who require frequent help and cannot live alone. They are persons with moderate to marked infirmity, associated with

³ Sampling was planned and supervised by J. A. Jahn, Ph.D. Research activities were coordinated by Helen Turner, M.S., with assistance of Syra R. Cohen, B.S.

⁴ The rating scheme was suggested by the work of F. D. Zeman, M.D.: *J. Mt. Sinai Hosp.*, 14: 3, 721, Sept./Oct. 1947.

advanced age or the presence of disease which severely limits physical ability. Examples are Parkinson's disease, paralysis, severe osteoarthritis, advanced peripheral vascular disease, malnutrition, and debility due to neoplasm.

Grade C. Restricted activity—complete: individuals who cannot function and survive in the absence of constant help given by a devoted family member or attendant. They may be totally bedridden and require complete nursing care. They have advanced infirmity with great limitation of mobility and complete dependence upon crutches, wheelchair, or cane as is frequent with advanced Parkinsonism, cerebro-vascular thrombosis and with advanced debilitation of malignant disease or "senility."

The psychologist's examination to determine mental status consisted of a special questionnaire and the face-hand test of Bender(2).

The special questionnaire was a series of 10 questions imbedded within a larger standardized series of 31 questions similar to the usual psychiatric examination of sensorium. The 10 questions selected from the longer list and used in this study for the quantitative determination of mental status, are as follows: 1. What is the name of this place? 2. Where is it? 3. What is today's date? 4. Month? 5. Year? 6. How old are you? 7. When were you born? (Month) 8. When were you born? (Year) 9. Who is President of the United States? 10. Who was the President before him?

The response to each of the questions was scored as right or wrong. In the analysis of data each subject was placed in one of 3 groups according to the number of errors made in response to the Mental Status Questionnaire "special ten." The 3 groups consisted of persons making 0-2 errors, 3-8 errors, and 9 or 10 errors and are here considered to differentiate between degree of severity of chronic brain syndrome, none or minimal, moderate, and severe.

The second test of mental status, the face-hand test, was used as described by Bender and his associates(2), who have demonstrated that it is a reliable test of brain disease. It consists of rating the person's ability to perceive two simultaneously applied tactile stimuli, one to the cheek and the other to the dorsum of the hand. The

test includes a series of double simultaneous stimuli in different combinations of right and left, and of cheek and hand, each of which is repeated twice, making a minimum of 10 such applications of stimuli in all. The test is done first with the subject's eyes closed and, if positive, is repeated with the subject's eyes open to determine whether opportunity to watch the application of the touch stimuli improves his performance.

In this study the test was considered positive only after the person had ample opportunity to learn that response to two simultaneous stimuli was expected, and with eyes open continued to make errors. A positive test is considered indicative of impaired mental functional status.

RESULTS

Physical Status and MSQ Score by Type of Institution: The physical and mental status of individuals as evaluated and rated appeared to parallel each other in all 3 types of institution (Table 1). In homes for the aged, 67% of persons making 0-2 MSQ errors were rated as in relatively good phy-

sical functional status (A) while only 6% were given poor physical ratings (C) and 27% were rated moderately (B). In contrast, of those making 9-10 MSQ errors, only 19% were of good physical status and 33% were rated poorly. Persons making 3-8 MSQ errors fell between the other two groups with respect to physical status.

Although as a group, the persons in nursing homes were in poorer physical and mental condition than the residents of homes for the aged, nursing home residents making the most MSQ errors were still most often in poor physical condition; only 9% of those with 9-10 errors were rated as A and 55% as C. There was little difference in the physical rating between those who made 0-2 and 3-8 MSQ errors, but both of these groups were rated as having considerably better physical status than the group which made 9-10 MSQ errors.

The state hospital patients showed the same relationships of physical and mental status. Of those who made only 0-2 errors, 50% were given a good physical rating and 20% were rated as in poor physical condition. Of those making 9-10 errors, only 17% were given good physical ratings, and 44% were rated as having poor physical functional status.

Physical Status and Face-Hand Test: When the face-hand test was used as the index of mental status, the same relationship to physical functional status was demonstrated (Table 2).

In each type of institution persons with negative face-hand tests were more likely to have a good physical rating than those who were positive in this test for chronic brain syndrome. A good physical rating was about twice as frequent in persons in whom the test was negative than for those in whom it was positive.

Comparison of Institutions: As evident in Table 1, the largest proportion of persons with poor mental status was found in the state hospitals, with the nursing homes next, and the homes for the aged third. The largest proportion of persons with poor physical functional status, on the other hand, was found in nursing homes, followed by the state hospitals, with the homes for the

aged third. However, when the institutions were considered individually, and compared to each other, large differences were found between institutions of the same type, and marked likenesses between institutions of different types. Two of the homes for the aged and 5 nursing homes had as many, or more, persons with a positive face-hand test as 2 of the 3 state hospitals. Four homes for the aged and the 3 state hospitals had a larger proportion of their populations rated as B and C in physical capacity than did two of the nursing homes.

Whatever the "label" of the institution, the institutions which had high proportions of persons of poor mental status also had many with poor physical status, and the converse was also true. When each institution in the sample was ranked according to the mean of the physical functional status ratings of its residents, and this was compared to the mean of the MSQ error scores of its residents, a rank order correlation of +.53 was obtained, significant at the 1% level of confidence. When the institutions were ranked according to the percentage of persons with positive face-hand tests the rank order correlation of the proportion of positive tests to poor physical functional

status was $+.57$, also significant at the 1% level.

The mental and physical status of the institutional populations were more closely correlated than was either of these two factors with the type of institution. The contingency coefficient of mental and physical status was $+.37$; for type of institution and either mental or physical status it was $+.33$.

Comparison by Age: When the persons studied were classified according to age, a significant relationship between physical and mental status was noted for each age group in each type of institution, with the single exception of nursing home patients in the 65-74 age range (Tables 3, 4 and 5). Poor physical status was also found to parallel impaired mental status more closely than it did chronological age. In fact, in nursing homes and state hospitals, the relation between physical

status and age was no greater than could be accounted for by chance. In homes for the aged, there was a significant parallel of older age and poor physical status, but the contingency coefficient of $+.36$ was smaller than that found for physical and mental status ($+.39$) in the same institutions.

The superiority of mental status over age as an index for the prediction of physical functional status can also be demonstrated by comparison of the oldest persons in good mental functioning (0-2 MSQ errors) with the youngest age group of poor mental status (9-10 MSQ errors). In the homes for the aged, for example, 46% of persons 85 years of age or older with 0-2 MSQ errors were in the best (A) physical functional category. By contrast, only 18% of those 65-74 years of age with 9-10 MSQ errors were rated as having good (A) physical functional status.

SUMMARY AND CONCLUSIONS

Our results show that the mental and physical functional status of institutionalized aged persons are highly interrelated. The relationship is seen within each of the 3 types of institutions studied, and for all age groups.

In the different types of institutions it was found that persons tended to have disabilities consistent with the type of services to be expected in the institution. Thus, patients in state hospitals had the largest number with poor mental functional status, while there was predominance of persons with poor physical functional status found in the nursing homes. Nevertheless, institutions of a given type differed widely from each

other. Some homes for the aged and nursing homes had a larger proportion of persons with poor mental status than did some state hospitals, while some state hospitals and homes for the aged had more persons with poor physical functional status than did some nursing homes. Therefore, it is possible to make a more accurate prediction of a person's mental status on the basis of his physical status, or of his physical status by his mental status, than on the basis of the type of institution in which he is residing.

Physical functional status is not significantly related to chronologic age in nursing homes or state hospitals. In homes for the aged the relationship is significant, but even then mental status is better than chronologic age in predicting the physical status. A person 85 years of age or over with good mental status is much more likely to have a good physical functional status than a person 74 or younger who is in poor mental condition.

It is concluded that physical and mental aspects of functioning cannot be compartmentalized in aged persons; impairment of either can be regarded as indicating a need for comprehensive medical care. Recent trends in the development of special medical facilities in state hospitals, and both medical and psychiatric services in homes for the aged are apparent recognition of this phenomenon.

TUBERCULOSIS IN STATE MENTAL HOSPITALS

JAMES W. MACDONALD, M.D.,

The mental hospital patient with tuberculosis presents a multifaceted problem of major importance to all who work with the mentally ill, as well as to those in epidemiology and in diseases of the chest. These patients with their problems have been much neglected. Until recently they were in the unfortunate position of the unwanted children of medicine. Chest specialists often dismissed the matter with such remarks as "But these people are crazy." When confronted with the problem, psychiatrists have usually confined their observations to speculative psychodynamics of no proven relevance to the pathogenesis of either the disease or epidemiology contagion. Worst of all has been the philosophy that these patients weren't going anywhere and, consequently, no physician should be too much concerned with their problems.

In order to rectify this attitude, the Commonwealth of Pennsylvania built a hospital expressly for such patients near Butler, Pa. Before it could be put to use, however, World War II had occurred and following it, the Federal Government moved in and is currently operating this hospital as a Veterans Administration Tuberculosis Center. Only gradually is the problem of the tuberculous in our state hospitals being solved. One focal point of such activity is the Tuberculosis Center at the Mayview State Hospital where we have studied 132 cases of active pulmonary tuberculosis culled from a patient population of 10,500 at 5 of the 7 state psychiatric hospitals² in the western half of our State.

Begun in 1949, the Tuberculosis Center at Mayview is a 140 bed, well equipped, self-sustaining unit, in some respects superior to the "ideal" proposed for such patients by the Committee on Hospitals of the Group for the Advancement of Psychiatry in January 1954(1), the same year our unit was completed and initially used.

Since 71 of our hospitalized psychiatric

patients with active tuberculosis at the Center, at the time of this study, were from Pittsburgh, it was possible to make certain statistically consistent comparisons between the tuberculous and non-tuberculous psychiatric patients at Mayview and between tuberculous psychiatric Pittsburghers and the Pittsburghers known to have tuberculosis but not confined to mental institutions.

A relatively high prevalence of tuberculosis among institutionalized patients and the depressed atmosphere which pervades so many non-psychiatric tuberculosis hospitals have been too frequently interpreted as indicating a mutual symbiosis between the two diseases at the expense of the patients, sharply delimiting therapeutic possibilities and worsening prognosis.

To what extent psychologic factors contribute to the development of pulmonary tuberculosis has remained a moot question, on which we hope this study sheds a little light. Wasserug and McLaughlin, as cited by Anderson(2), stated,

No one as yet has advanced any proof that there are physiological alterations in insanity which predispose a person to tuberculosis in the way, let us say, that silicosis does. Nor, conversely, has it been demonstrated that tuberculosis predisposes to mental disease.

Some feel that the induced dependency and frequently seen depression noted in the non-psychotic tuberculous are caused by the patient's infection and compounded by his hospitalization for it. His capacity to endure stress may thus be reduced and, in a susceptible individual, be so weakened that a psychotic break is precipitated. Pathogenesis of both conditions has been explained in such widely disparate terms as geologic, genetic, and geriatric. Tuberculosis is a physical, not a mental, illness. It flourishes in any crowded environment where the individual's needs are not adequately cared for, be it a tenement, a jail, or the back ward of a psychiatric hospital. Psychosis, on the other hand may be due to either functional or organic factors and

¹ Mayview State Hospital, Mayview, Pa.

² Somerset, Torrance, Warren, Hollidaysburg, and Mayview State Hospitals.

may be symptomatic of a disease entity or merely descriptive of an abnormal symptom complex, the exact biologic significance of which remains obscure. When tuberculosis is seen in the mental hospital patient, certain questions immediately arise. Foremost among these are:

1. What are the tuberculosis prevalence and mortality rates for such a population?
2. Which illness necessitated the initial hospitalization?
3. What is the length of time between the hospitalizations for the initial and complicating illnesses?
4. Do the age, sex, and race trends for these patients follow those for the non-tuberculous populations in the same hospitals and for the known cases of active tuberculosis in the general population?
5. What type of psychiatric illness is found most prevalently among the tuberculous in these hospitals?

The present study has undertaken to deal with these questions.³

REVIEW OF LITERATURE

Since the definitive article by Barnwell, *et al.* 6 years ago, there is found nothing noteworthy in a perusal of the Quarterly Cumulative Indices while articles on all the complications of tuberculosis from acromegaly to unweitis abound.

In 1953 Close, Hecker, and Glover(3) had reported a prevalence of 4 cases of active pulmonary tuberculosis per one thousand patients between 1945 and 1950 at the Veterans Administration Neuropsychiatric Hospital at Coatesville, Pa.; in 1951 they reported a prevalence of 3 cases per thousand.

In 1952 Tomkins(4) had reported a prevalence of 9.5 cases of active tuberculosis per thousand World War I veterans in all VA neuropsychiatric hospitals in comparison with 4.3 cases per thousand World War II veterans in all VA neuropsychiatric hospitals. In the same journal, Anderson(2) stressed the magnitude of the problem. He emphasized the vital importance of early detection and the higher incidence of tuberculosis in patients over 45 years of age. He

reported a prevalence of 27 to 40 cases of active tuberculosis per thousand psychiatric patients examined in psychiatric hospitals generally throughout the United States.

Oeschli(5) in 1949 had stressed the greater prevalence of tuberculosis among psychiatric patients hospitalized for several years. Bettag(7), in 1948, found the same prevalence of tuberculosis among psychotics as Anderson(2) was later to report.

It has been estimated that approximately 30,000 Americans in mental hospitals suffer from tuberculosis concurrently(1).

METHOD

This is a statistical study. The results represent a tabulation and logical breakdown of data gleaned from the records of patients at the Tuberculosis Center at Mayview State Hospital from March 1958 to March 1959. Comparative data for the non-tuberculous patients at Mayview were likewise analyzed. Similar statistics were obtained from the Office of Biostatistics Allegheny County Department of Health for the tuberculous patients not confined to mental hospitals in the City of Pittsburgh (6). Biostatistical consistency forced us to limit certain aspects of our study to the 71 tuberculous psychiatric patients from Pittsburgh. The remaining 61 had been transferred to the Tuberculosis Center from 4 other state hospitals in more rural Western Pennsylvania; the necessary comparative data were unobtainable for this latter group.

PREVALENCE AND MORTALITY

As of March 1, 1959 one hundred thirty-two cases of active pulmonary tuberculosis were found in a patient population of 10,500 at 5 state mental hospitals, for a prevalence rate of 13 per thousand.

When we consider only those cases admitted to the Tuberculosis Center from the non-tuberculous psychiatric wards at Mayview State Hospital, which services the City of Pittsburgh exclusively, we find 71 cases for a prevalence rate of 21 per thousand. During 1958, the Tuberculosis Registry listed 1,744 reported cases of known active tuberculosis for the general population of Pittsburgh(6). From this, we have estimated a prevalence rate of 2.7 cases per

³ The author wishes to acknowledge his gratitude for the technical assistance of Miss Diana Haberman and Miss Christine A. Cuomo.

1,000 for the city's general population.

From March 1, 1958 to March 1, 1959, there were 15 male and 12 female tuberculosis deaths in this population, giving us a tuberculosis mortality rate for the state mental hospitals of 270 per 100,000. The crude tuberculosis mortality rate for the general public in this same area at the same time was 10 per 100,000.

Concerning the fluidity of the patient population during the year, in addition to the deaths cited above, two patients were returned to their homes on general leave of absence, their tuberculosis inactive and their mental illness controlled. Six others, their mental illness in remission, were transferred to nonpsychiatric tuberculosis* hospitals. An additional 70 patients with inactive tuberculosis were returned to the nontuberculous wards whence they had come. Several of these patients had never

had tuberculosis and had been needlessly kept in isolation for long periods of time. A tuberculosis convalescent unit is sorely needed.

TIME RELATION BETWEEN HOSPITALIZATION FOR INITIAL AND COMPLICATING ILLNESSES

In 19 of our cases, active tuberculosis and severe mental illness were diagnosed during the period of the patient's initial hospitalization. Of the others, the patients whose psychiatric illness precedes a diagnosis of their active tuberculosis constitute more than 90% of the series (Table 1). Such patients may develop active tuberculosis at anytime; we found the median length of time in years between the initial hospitalization for mental illness and the diagnosis of active tuberculosis as a complication to be 15.8 years for the males and 10.0 years for the females (Table 2).

TABLE 1

NUMBER OF PATIENTS* AT MAYVIEW TUBERCULOSIS CENTER IN WHICH A PSYCHIATRIC ILLNESS PRECEDED TUBERCULOSIS COMPARED BY DIAGNOSIS WITH THE NUMBER OF PATIENTS WHOSE TUBERCULOSIS PRECEDED THEIR PSYCHIATRIC ILLNESS

Total 9.7%	3	7	1	0	11
Mental Illness Preceding Tuberculosis					
Male 61.1%	14	49	1	5	69
Female 29.2%	3	27	0	3	33
Total 90.3%	17	76	1	8	102

*1958

TABLE 2

YEARS BETWEEN ONSETS OF INITIAL AND COMPLICATING ILLNESSES FOR 113 PSYCHIATRIC TUBERCULOUS PATIENTS AT MAYVIEW STATE HOSPITAL

Psychosis Preceding Tuberculosis 102 patients		Tuberculosis Preceding Psychosis 11 patients			
Male	Female	Male	Female		
Number of Cases	69	Number of Cases	33	Number of Cases	8
Median Years	15.81	Median Years	10.00	Median Years	2.25

Considering the 11 cases where the patients were committed to a psychiatric institution from a tuberculosis hospital, we found a much shorter time interval. The median in years between the hospitalization for tuberculosis and the manifest onset of a serious mental illness as a complication necessitating transfer to a psychiatric center was 4.0 years for the males and 2.25 years for the females. Thus we see that, regardless of which is the initial illness, the median length of time in years between the onsets of the initial and complicating illness was significantly greater for the male. The relatively greater percentage of females committed to mental hospitals within 5 years of their initial hospitalization for active tuberculosis was striking (Graph 1). That a greater number of men were actually committed to our Center from tuberculosis institutions during this period was but consistent with the greater prevalence of active tuberculosis among males generally.

AGE, SEX, RACE

In Table 3 we have tabulated the median age for the tuberculous and non-tuberculous psychiatric population at Mayview State Hospital. The tuberculous psychiatric patient was definitely older than the tuberculous patient in the general population in Pittsburgh who was not confined to a men-

tal hospital; his median age was 53.8 years contrasted to the median age of 46.7 years for the latter group. However, he was younger than the non-tuberculous psychiatric patient at Mayview State Hospital, who had a median age of 57.6 years.

In terms of sex differences, the tuberculous psychiatric patient was more like the known case of active tuberculosis in the general population not confined to a mental hospital than he was like the non-tuberculous psychiatric patient at Mayview State Hospital. The known tuberculous cases from both the hospitalized psychiatric populations and the general populations were predominantly male. In our series, the male to female ratio was almost 2 to 1 (Table 4). In the general population, male predominance was less striking but marked (6). Approximately 53% of the patients in the state hospital population considered were females.

There was no striking age-sex difference in either psychiatrically ill population. In the non-white element of the general population, however, an appreciable sex difference in median age existed (46.9 years for the males and 34.0 years for the females).

We have failed to find any statistically significant racial difference in the prevalence of active tuberculosis among the psychiatric populations of our state hospitals.

GRAPH 2

PERCENT OF POPULATIONS OF TUBERCULOUS AND NON-TUBERCULOUS PSYCHIATRIC PATIENTS HOSPITALIZED AT MAYVIEW STATE HOSPITAL IN 1958, GROUPED ACCORDING TO PSYCHIATRIC DIAGNOSIS

This, in itself, is of considerable significance since it did not hold for the city from which almost two-thirds ($2/3$) of our cases of active tuberculosis were derived; here there continued to be a relatively greater prevalence rate among the city's non-white population (6).

NEUROPSYCHIATRIC DIAGNOSIS

From what mental illnesses do the tuberculosis patients of our Center usually suffer? Graph 2 indicates that the greater percentage of both tuberculous and non-tuberculous psychiatric cases fall into the diagnostic classifications of functional psychotic disturbances and chronic brain syndromes. In these diagnostic classifications, schizophrenic reactions are predominantly most common in both tuberculous and non-tuberculous populations; however, a few of our tuberculous patients suffer from affective disorders *e.g.*, manic-depressive disease and involutional psychotic reactions. Where it could be learned, the cause of the chronic brain syndromes among the actively tuberculous was usually arteriosclerosis, syphilis, or alcohol, but none of these 3 causes of chronic brain syndromes was present in statistically significant numbers. Proportionately, fewer of the tuberculous patients suffer concurrently from chronic brain syndromes than do the non-tuberculous patients at Mayview State Hospital. This is especially true for the females in accord with the currently popular concept of active reinfection tuberculosis being a disease of old men. A minority of our patients were hospitalized because of mental deficiency with psychosis, personality disorders, acute brain syndromes, or psychoneurosis (Graph 2).

DISCUSSION

Along with the decline in its mortality rate, the entire epidemiologic picture of tuberculosis has undergone marked changes during the past 3 decades. While one after another tuberculosis sanatorium or hospital was being shuttered or converted to other uses, the disease which formerly exacted its greatest toll from the young adult-female population gradually changed to one most prevalent among old and indigent males.

Comparable changes were occurring in the scene at the state mental hospitals. As

the surrounding walls and barred windows have gradually disappeared, increasing frequency of mental illness in the aged has been observed while pellagrins have become rare and the tertiary luetics now constitute a much smaller proportion of the total patient population.

The greater prevalence of active tuberculosis in urban areas persists, as does the increased frequency of this disease and its relatively high mortality rate in prisons and mental hospitals. Whereas 20 cases per thousand of active tuberculosis among state hospital patients for every 1 case per thousand in the general population was cited by Barnwell, *et al.* (1) in 1954, we found this ratio to be less than 8 to 1 for the actively tuberculous psychiatric patients from the City of Pittsburgh in 1958 and the actively tuberculous in the city's general population. When we consider mortality rates, however, this ratio is 27 to 1.

Increased awareness of the possibility of patients contracting the disease has had several manifestations, notably an improvement in the general care and nutrition of the chronically ill psychiatric patient and the annual chest X-ray survey of the entire state hospital patient population.

Our prevalence rate of 13 cases per thousand for the 10,500 state hospital patient population studied and of 21 cases per thousand for the urban component of that group compares favorably with the 27 to 40 cases per thousand found by Anderson (2) 7 years ago, but not so favorably with the 3 cases per thousand reported by Close, *et al.* (3) for World War II veterans in 1951. The difference in patient populations seems to us a basic disparity to be grasped in resolving the latter. Our patients were much older and had been suffering from mental illness for many years before developing active tuberculosis.

Those few patients who were committed to mental hospitals and transferred to our Center after being initially hospitalized for their tuberculosis did so within 6 years. The women had developed mental illness earlier than the men. The tuberculosis experience of this group appears to have been incidental and non-specific in unmasking serious mental disease.

In comparing the tuberculous with the

non-tuberculous in our psychiatric hospital patient populations, we learned that no psychiatric nosologic peculiarities were consistently applicable to the tuberculous.

Ideally, the psychiatric hospital should provide an almost perfect environment for convalescence from pulmonary tuberculosis. Properly staffed and supervised, it should reduce to a minimum such problems as exposure of the uninfected, alcoholism, elopement, undernutrition, refusal to take medication, and control of its complications, each of which may be a major problem in the non-psychiatric tuberculosis hospital. That our situation was somewhat less than ideal was illustrated by the mortality rate and the fact that only 2 cases in a series of 102 who had been initially hospitalized for mental illness had their pulmonary tuberculosis discovered and isolation begun when the tuberculosis was still in its minimal stage.

SUMMARY AND CONCLUSIONS

One hundred thirty-two cases of active pulmonary tuberculosis from a patient population of 10,500 in 5 state hospitals were studied. Seventy-one of these were from the Mayview State Hospital servicing Pittsburgh. Biostatistically consistent comparisons could thus be made with data obtained for known cases of active tuberculosis in Pittsburgh not confined to mental hospitals. To answer those questions posed in the introduction :

1. There is a prevalence rate of 13 cases per thousand of actively tuberculous patients in the population from 5 of Pennsylvania's state psychiatric hospitals.

The prevalence rate was 21 cases per thousand of active tuberculous patients at Mayview State Hospital. This population was derived entirely from Pittsburgh where the prevalence rate for active tuberculosis in the general population not in mental hospitals was 2.7 cases per thousand. The tuberculosis mortality rate for these patients was 270 per 100,000. Male mortality rate was 300, and female rate 240 per 100,000. The general public's crude tuberculosis mortality rate was 10 per 100,000.

2. In 19 of our cases, no chronological primacy could accurately be assigned either disease.

Of the others, more than 90% had been confined to mental hospitals for several years prior to their tuberculosis being discovered. Only 2 of 102 of these cases had minimal tuberculosis when it was discerned.

3. The median length of time in years between the hospitalization for severe mental illness and the discovery of the complicating tuberculosis was 15.8 years for the males and 10.0 years for the females. When severe mental illness occurred as a complication in individuals initially hospitalized for their tuberculosis, the median time in years between hospitalizations for the tuberculosis and psychiatric disturbance was 4.0 years for the males and 2.25 years for the females.

4. The actively tuberculous in the general population of Pittsburgh not confined to mental hospitals had a median age of 46.7 years; they were predominantly males and a relatively greater prevalence of active tuberculosis was found in the non-white population.

Our tuberculosis patients derived from this urban area had a median age of 53.8 years. The male to the female ration approaches 2 to 1. The non-tuberculous hospitalized psychiatric patients in this group have a median age of 57.6 years and 52.9% of these patients are females. There was no statistically significant racial difference between the tuberculous and non-tuberculous psychiatric hospital populations.

5. Almost all the actively tuberculous psychiatric population hospitalized in this series suffered from functional psychotic disturbances (especially schizophrenic reactions) or from chronic brain syndromes, but there were no psychiatric peculiarities consistently applicable to the tuberculous.

If we are ever to eradicate tuberculosis from our state hospital population, earlier detection and more effectual control of all hygienic factors in the environment of hospitalized patients are imperative. The control of this major epidemiologic disease must be administered by those conversant with it.

THE OPERATIONAL MATRIX OF PSYCHIATRIC PRACTICE

II. VARIABILITY IN PSYCHIATRIC IMPRESSIONS AND THE PROJECTION HYPOTHESIS¹

GEORGE N. RAINES, M.D.,² AND JOHN H. ROHRER, Ph.D.³

In a previous paper(3) an attempt was made to isolate pertinent variables responsible for differences between psychiatrists in reported psychiatric diagnostic impressions. In that study, reasonable experimental control was exerted over the following variables: (a) training; (b) experience; (c) nomenclature and definitions; (d) length of interview; (e) physical conditions under which the interviews took place; (f) motivation of the client interviewed; and (g) clients interviewed. Despite these equated controls, significant variations in psychiatrists' impressions were found. Moreover, the pattern of differences was unique for each psychiatrist and the pattern that characterized a given psychiatrist persisted in time. In an attempt to explain the observed differences between psychiatrists, a "projection hypothesis" was developed. This hypothesis derived from the assumption that variation between psychiatrists, with respect to diagnostic judgments, reflected differing frames of reference resulting from the unique transactional life experiences of the individual psychiatrist. It was hypothesized that this tendency makes the psychiatrist more sensitive to certain facets of the patient's intrapsychic dynamics, and also results in a greater perceptual distortion of other facets of the patient's personality structure, which are projected in the diagnosis.

This paper reports a study designed to test more specifically the projection hypothesis.

METHOD AND PROCEDURE

Subjects. The subjects used were 116 enlisted regular Navy men, all on duty at a Naval installation on the Eastern seaboard. The men formed a homogeneous group. Their average age was 23.7 years, and ranged from 19 to 28 years. Their NGCT scores ranged from 36 to 67 with an average of 51.8. They were all functioning satisfactorily in the billets to which they were assigned; none had been sent to Sick Bay for suspected psychiatric disabilities. The men were assigned at random for a 30-minute psychiatric interview with one of 4 psychiatrists. They were told that the interview was a part of an experimental study being carried out for the Navy.

Examining Psychiatrists. The 5 psychiatrists used in this study, were civilian psychiatrists. Table 1 summarizes their psychiatric experience.

All had received psychoanalytic training in the same institute. The fifth psychiatrist had given personal training analysis and supervision to the other four and thus had become well acquainted with each of them. He was requested to prepare an assessment of the personality structure of each of the junior psychiatrists using the knowledge he had gained from working with them. This constituted one set of data.

A second set of data was supplied by the psychiatric assessments of the enlisted men made by the 4 junior psychiatrists. These data were collected for use primarily in connection with studies of leadership. Prior to the start of the assessment program two 2-hour discussions were held by the psychiatrists where they reached common agreement on the areas of the personality structure to be examined in the interview, the nomenclature to be used, and the definitions of the chosen nomenclature. They dictated their clinical impressions immediately following each interview.

Thus, two independent sets of data were available for analysis: (a) transcribed psy-

chiatric impressions of 116 enlisted men who had been assigned at random to 4 examining psychiatrists; and (b) written personality assessments on each of the 4 examining psychiatrists, prepared by the senior psychiatrist who was well-acquainted with their psychodynamic way of functioning.

Data Analysis. The major analytic tool used for evaluating the assessment data was the method of content analysis(2). The 116 clinical summaries were analyzed by tabulating the frequency with which references were made to each of 41 categories. These categories were chosen because they were used in the recorded summaries as diagnostic, descriptive categories one or more times. The categories used could be grouped under the following general headings: (a) physical appearance; (b) family referents and attachments; (c) dominant defenses utilized in interpersonal situations; (d) sexual adjustment and attachments; (e) intellectual factors; and (f) diagnostic terms used in the psychiatric

diagnosis. Statistical analyses of the frequency data were made through the use of Chi-square where applicable. For those categories found significant statistically, profiles were plotted for each psychiatrist.

RESULTS

The results of the Chi-square analysis are presented in Table 2. Of the 11 categories with sufficiently high frequency to permit statistical evaluation, 3 (passivity, dependence, and social insecurity) did not show statistically significant differences between psychiatrists. This finding was in agreement with the verbalized consensus of the psychiatrists' opinions to the effect that the subjects, as a group, could best be characterized as passive dependents seeking secure positions in society.

The finding of significance in the remaining 8 categories permitted the questioning of the assumptions underlying the use of the Chi-square test, namely that the varied personality configurations of the enlisted

men were distributed equally between psychiatrists, or our assumption that the evaluative frame of reference used by the different psychiatrists was the same. The men had been assigned to psychiatrists through the use of a table of random numbers, to

guard against systematic bias. In a previous study(3) we demonstrated that potential lack of randomness was not responsible for similarly observed differences. Thus, the second assumption seemed the more reasonable one to reject. Figure 1 presents pro-

FIGURE 1
GRAPHIC PROFILES, BY PSYCHIATRIST, OF USAGE OF CATEGORIES IN WHICH
STATISTICAL SIGNIFICANT DIFFERENCES WERE OBSERVED

files⁴ for each psychiatrist showing the relative frequency with which they used the significant categories.

The profiles reveal the idiosyncratic pattern, by psychiatrist, suggested by the statistical analysis. An explanation of these patterns is given in the "projection" hypothesis—i.e., that differences observed in diagnostic judgments reflect a tendency, on the part of the psychiatrist, to attribute to his patient some of the psychiatrist's own personality characteristics. This results in a greater sensitivity, on the part of the psychiatrist, for certain facets of the patient's personality structure and a greater perceptual distortion of other facets of the patient's personality structure. In this study, to test further the projection hypothesis, a comparison was made between a verbalized summary of the facts revealed in the content analysis profile and the verbalized summary prepared by the senior psychiatrist. The pairs of descriptive paragraphs for each psychiatrist are juxtaposed and presented below.

Psychiatrist 1: Content Analysis Summary.

This psychiatrist places greatest emphasis on masculinity-femininity and personal appearance characteristics, with moderate overemphasis on intelligence and ambitions. He fails to note (on a relative basis) anxiety, paranoia, depression or hostility. He fails to see any evidence of rejection or female attachments.

⁴ Because the total number (frequencies) of usages of categories differed for each psychiatrist, it was necessary to correct for this factor in order to make directly comparable profiles for the psychiatrists. The formula used for correcting the frequencies was:

$$\text{Profile Category Value} = \frac{\text{pcOf}}{\frac{(\text{pTf})(\text{cTf})}{\text{psTf}}}$$

Where:

pTf = Total frequencies in all categories for psychiatrist X;

psTf = Total frequencies in all categories for all psychiatrists;

cTf = Total frequencies in a given category for all psychiatrists;

pcTf = Observed frequency in a given category for psychiatrist X.

The resulting profile category value would have a value of one, if psychiatrist X had shown the same proportion of use as did the other psychiatrists. The "diagnostic factors" category has been broken down into discrete nomenclature terms in the graphic presentation.

Senior Psychiatrist Evaluation. This psychiatrist is a middle-aged man who has been quite concerned about masculinity. He has need to avoid recognizing any personal need for affection from others, yet his pattern has been to "mother" other people considerably. He is inclined to be rigid and to place too much emphasis on such qualities as ambition and intelligence. He is too concerned with politeness, manners, and personal appearance, and at times not enough concerned with what goes on inside of people. His chief difficulty is his tendency to treat all people as "nice" people and to not recognize their hostilities or other psychiatric disturbances. This tendency to overly minimize the importance of psychiatric disturbances had on occasion interfered with his establishing an effective relationship with patients.

Psychiatrist 2: Content Analysis Summary.

This psychiatrist places greatest emphasis on rejection, repression, paranoia, and female attachments. He overemphasizes, to a lesser degree, anxiety, aggression, hostility, and depression. He tends to fail to report personal appearance, dependency feelings, feelings concerning masculinity-femininity, intelligence, and ambition strivings. *Senior Psychiatrist Evaluation.* This psychiatrist is middle-aged and is married. He is the older of two brothers. He had overly strong feelings of maternal rejection and still is quite competitive with a brother who managed to get ahead of him in school. He is of good intelligence. One of his chief difficulties has been his paranoid tendencies expressed by presenting himself, at times, as stupid and stubborn to avoid supposed exploitation. This has frequently resulted in people rejecting him. He has a studied disregard for his personal appearance, apparently trying to maintain the "country" appearance of his earlier childhood environment. He has a considerable need on the one hand to overlook hostility, and on the other hand to emphasize it unnecessarily. One of his difficulties in interviewing is his tendency to treat an interviewee as a "good boy" and to substitute a superficial type of friendliness for an attempt toward deeper understanding. His dependency needs are strong but he would likely neglect them. He has shown periodic periods of depression and is capable of sudden strong likes or dislikes.

Psychiatrist 3: Content Analysis Summary.

This psychiatrist places greatest emphasis on female attachments, depression, and hostility, with lesser overemphasis on security in social situations, dependency, passivity, and anxiety.

He tends to underemphasize male attachments, ambitions, and intelligence. He tends to ignore rejection and paranoia. *Senior Psychiatrist Evaluation.* This psychiatrist is in his middle thirties, an only child, and married. One of his big difficulties has been his dependent attitudes and his need to ingratiate himself in the presence of "superiors." Also, he tends to be overconscientious in reporting his felt limitations. He is particularly good at interviewing and probably picks up most pathology. His difficulties in an interview might be in handling some rather sudden hostile attitude on his part toward a client, or some unevenness due to a period of mild depression in himself.

Psychiatrist 4: Content Analysis Summary.

This psychiatrist places greatest emphasis on anxiety, paranoia and dependency, with lesser overemphasis on passivity, intelligence, and ambition. He failed to note any masculinity-femininity factors or any rejection. He tends to underemphasize personal appearance, aggression, hostility and repression. *Senior Psychiatrist Evaluation.* This middle-aged psychiatrist has recently been married. He was the younger of two sons and his mother's favorite. Earlier he had considerable anxieties about his dependency needs and handled them, as he grew up, by isolating himself more and more. He still has a tendency to overemphasize the importance of dependency needs. He has always tried to be "the best" person. When this was impossible he tried to finish second to a more brilliant colleague with whom he would establish an identifying relationship. He is acutely sensitive to paranoid tendencies and emphasizes them considerably. He tends towards a narcissistic obsessive picture with a tendency to intellectualize rather than to make use of his sensitiveness. I would expect him to identify with persons like himself in interviewing and perhaps to overemphasize intelligence.

DISCUSSION

The high degree of agreement between the summaries written on the basis of results from: (a) a content analysis made from each psychiatrist's written evaluation of clients; and (b) the independent evaluation of the psychodynamic structure of each assessing psychiatrist made by the senior psychiatrist, are favorable to the projection hypothesis.

Admittedly, the number of assessing psychiatrists was small, and perhaps the gener-

ality of the findings might have been enhanced if more senior psychiatrists, thoroughly acquainted with the assessing psychiatrists, had been available for use. The face validity of the results, however, minimize this latter consideration.

Coupled with the findings in our previously reported paper(3), the argument for the projection hypothesis becomes more convincing, since in the current study we were able to provide a valid *independent measure* of the psychodynamic structure of the psychiatrists and to demonstrate, with the assessing psychiatrists studied, that the projection hypothesis was substantiated.

The systematic objective data recorded herein offer evidence for the common observation that individual differences do exist between psychiatrists with respect to the relative effectiveness with which they are successful in recognizing various functional psychiatric syndromes. The data suggest that these individual differences can be attributed, at least in part, to internalized frames of reference (psychodynamic structure) acquired as a result of developmental social transactions. Vicarious experiences gained through the study of psychiatric theory and method are effective in decreasing the distortion of the perceptions and judgments of the assessing psychiatrist to the extent that they are effective in bringing about an alteration of this internalized frame of reference, the most important alteration being at an unconscious level. It is paradoxical that it is from such individualized, personalized frames of reference that theoretical advancements to the science of psychiatry must come, yet the same reference frames serve as one of the major impediments to a more rapid development of a science of psychiatry.

The data also make explicit the need on the part of the evaluating psychiatrist, to objectively consider his own psychodynamic structure, as well as the perceived psychodynamic structure of his client, when he is arriving at diagnostic judgments of the client, inasmuch as those judgments are formed from the interpersonal transactional matrix of the interview situation. The data suggest that for the most reliable psychiatric diagnosis and prognosis of a given client, it would be desirable to utilize pooled inde-

pendent judgments made by several psychiatrists with known different psychodynamic structures, and that these pooled judgments would best represent the psychodynamic structure of the client.

A study by Cohen, *et al.*(1) concerned with a somewhat different problem presents results that are entirely consistent with our hypothesis. The Cohen study was concerned with the recording and study of interviews carried out by psychiatrists with 3 successful Naval Officers. The average amount of interviewing with each officer was approximately 225 hours. The recorded interviews were each listened to separately by 3 different psychiatrists and interpretations were made of the psychodynamic processes revealed, as the interview proceeded. Later the psychiatrists jointly discussed their interpretations. The background of the psychiatrists and the results of their joint discussions can best be described by direct quotes from the Cohen report.

... all the participants in the project had received the major portion of their psychiatric training under the same teachers, and three had worked together in ordinary professional association for ten years.

... It was amply demonstrated that the participating psychiatrist, no matter how experienced, not infrequently failed to note the significance of some communication of the subject, and in retrospect, failed to recall the content and emotional quality of the interview with accuracy. This represents, of course, a source of error and delay in carrying out psychotherapy or any other interview procedure. The causes for the psychiatrists' inadequacies in evaluating the subjects' meanings apparently have to do with the emotions, tensions, and patterns of reaction in his own character.

These findings by Cohen, *et al.*, while in full support of our projection hypothesis, suggest that the processes involved include more than a projection mechanism. In our earlier paper(3) we alluded to such a conclusion by stating "... the psychiatric decision involves not only the psychiatrist's emotional problems and defenses, but also his entire value system and probably his self-image." In that paper our results, properly, could be generalized only to the projection hypothesis. Results presented in this paper offer evidence that the psychia-

trist's value system (*e.g.*, values of personal appearance, intelligence, ambition,) do in fact become involved and color the reports of clinical impressions; *i.e.*, that the psychiatrist unconsciously identifies with certain aspects of the client's psychodynamic functioning and reacts to that identification in terms of the way he positively or negatively values the characteristic in his own functioning.

It is probable that our findings concerning the role of the psychiatrist's psychodynamic structure enter into and influence another most important area of psychiatry, namely the area of theorizing and theory building concerning matters of psychodynamic structure and function.

As was noted in our previous paper(3), the technique of content analysis, as applied to clinical diagnostic summaries, would be useful when applied to the evaluation of psychiatrists being selected for, or in, training programs.

SUMMARY

The study was designed to test the hypothesis that observed variations between psychiatrists, with respect to diagnostic judgment, reflected a tendency on the part of the psychiatrists to attribute to his client some of the psychiatrist's own personality characteristics, and that this tendency made the psychiatrists more sensitive to certain facets of the personality structure of the psychiatrists and also resulted in a greater perceptual distortion for other facets of the patient's personality structure.

The design utilized involved 5 civilian psychiatrists all of whom had received advanced psychoanalytic training in the same institute. The 4 junior psychiatrists in this group were used as assessment psychiatrists in a special assessment program of 116 enlisted men on duty in a Naval installation. The senior psychiatrist was used to assess the psychodynamic structure of the 4 junior psychiatrists.

The data on the 116 enlisted men comprised diagnostic clinical summaries dictated immediately following an interview that lasted approximately 30 minutes. These data were analyzed through the use of content analysis techniques. Thus, two independent measures of the psychodynamic

structure of the junior psychiatrist were available: (a) the senior psychiatrist's impressions written up in the form of a clinical diagnostic summary; and (b) the "projected" reflections of the psychiatrist's psychodynamic structure as revealed in the content analysis of his clinical summaries.

Those content analysis categories that were found to differ between the junior assessing psychiatrists at a statistically significant level were compared with the comparable data to be found in the assessment made by the senior psychiatrist. A high degree of agreement was observed between the two independent measures.

The results of this analysis were interpreted as supporting the projection hypo-

thesis. They also suggest that the hypothesis needs to be expanded to include identification processes, and the psychiatrist's value system and self image. The results are briefly discussed in terms of their implication for psychiatric training, psychiatric theory building relative to psychodynamic principles, and reliable psychiatric diagnosis.

AN EXPERIENCE OF PSYCHIATRY IN BRITAIN AND AMERICA

HENRY R. ROLLIN, M.D., D.P.M.¹

It would be difficult to exaggerate the impact of Freudian psychoanalytic theory and practice on contemporary American psychiatry, and in turn, because of the almost frightening "psychiatric awareness" of the population, on the American scene itself. Consider, for instance, the veritable flood of films from Hollywood in the recent past in which a psychoanalyst has played a major role. He—or even she—in suave, measured tones creates order out of chaos and with magical facility explains the inexplicable. Even the language has been influenced: an odd assortment of phrases of pseudo-analytic jargon has been incorporated into everyday parlance. Thus, people no longer get on well together, they "relate themselves well to each other"; or they are "relaxed and well integrated" when they might have been written off as "rather nice."

The demand for psychotherapy, which is almost synonymous in the States with psychoanalysis, is enormous and far exceeds the supply of *bona fide* therapists. The situation is reflected in a cartoon in an American magazine in which a young, enterprising analyst is shown with a notice on the door of his office which reads "Three couches: No waiting!" Incidentally, it is an intriguing problem and one worthy of investigation, why psychoanalysis, a European transplant, should have flourished so luxuriantly in America and so far outgrown its parent root in Europe. To illustrate this point let it be noted that there are more psychoanalysts in practice in Philadelphia alone than in the entire United Kingdom. It should be added that there are many psychiatrists in Britain who subscribe to Freudian concepts as a psychological theory, but not as a psychotherapeutic procedure.

It must be pointed out, too, that the methods of referral to a psychiatrist in America differ radically from those which obtain in England where a letter of in-

troduction from the family doctor, or a brother specialist, is the accepted procedure. In America anyone who, in his own wisdom, considers he should consult a psychiatrist makes his own appointment at the clinic or office. Furthermore, the reasons for a psychiatric consultation are much more broadly based. The existence of "problems," that is to say difficulties of a day-to-day sort not causing distress or illness in the true sense of the words, are sufficient to warrant a consultation, or, maybe, the inception of a personal analysis. In all, it would appear that the American psychiatrist is endowed by the public with an omniscience and infallibility which mercifully does not obtain in England.

"Money speaks sense in a language all nations understand." What then is the relative cost of psychiatric treatment in our two countries? This is not the time or place to argue the rights or wrongs of the British National Health Service. Nevertheless, it cannot be gainsaid that since it came into being, adequate, or more than adequate, treatment is available to all "for free" on an in-patient or out-patient basis. Such private mental hospitals as remain offer little more than perhaps increased creature comforts for the high cost which ever rising prices compel them to charge. In America, on the other hand, the availability and quality of treatment is dictated by income. For the lower-income groups it is true that psychiatric treatment is offered free in the city or state hospitals which vary enormously, however, in their standards. For the rich there is no problem: the best treatment in the world is at their disposal, but at staggering cost. It is the middle-income groups for which a lengthy psychiatric illness might spell financial ruin in spite of a variety of medical insurance schemes which either exclude or provide reduced benefits for such an illness.

To consider the place of psychiatry amongst its sister disciplines in medicine: It is all too evident that in America, psychiatry, the erstwhile ugly sister, has been so glamorised that she is fast becoming the

¹ Horton Hospital, Epsom. Fulbright Fellow in Psychiatry, U.S.A. 1953/54.

family favourite and now takes her rightful seat at, or near, the head of the family table. In England psychiatry still sits "below the salt." For some years now in America full psychiatric services have been available in most teaching hospitals and university clinics, and these services are rapidly spreading to other hospitals at a rate faster than in England.

As to the teaching of psychiatry, both undergraduate and post-graduate, the programmes in the states are much more ambitious than is the case in England where the battle for an appropriate place in the curriculum is still being waged. Furthermore, there is an ever-increasing trend in America to teach psychiatry not as an encapsulated subject, beginning and ending with the psychoses and neuroses, but to teach in addition the psychiatric implications of the many ills to which man is heir. Psychosomatic medicine, therefore, which was re-born in America, looms much larger in the theory and practice of medicine in general in America than in England.

What is more calculated to turn the visiting Englishman green with envy are the glittering academic palaces which stud the American psychiatric scene with their apparently unlimited resources for research in terms of money, man-power and equipment. Because of this academic affluence, research projects can be attacked on a broad front. In England, where the tradition of research on the bent-pin-and-bits-of-string tradition persists, research must be narrowed and the precise target carefully pin-pointed. In the circumstances, it is not surprising that some of the world's best research is carried out in the States. What is surprising is that England still makes her contribution, and a substantial one at that.

The emphasis on psychoanalysis as a psychotherapeutic procedure in America has been stressed. As to other psychiatric techniques there is seemingly little difference between the two countries, except, perhaps, in the degree of their use.

The attempt to drown both the neuroses and the psychoses in a sea of tranquilisers has failed and some sober re-thinking is

going on on both sides of the Atlantic. But there is now a rising tide in the use of the thymoleptics, or psychic energisers; already, in England at any rate, there is an undertow of criticism of these drugs because of their toxicity and side-effects and a call to stem the tide is being made until further assessment can take place.

In both England and America deep-insulin coma treatment for schizophrenia is on the way out: the leucotome is less in evidence, too; but electroshock in England, particularly in combination with intravenous anaesthesia and muscle relaxants, holds an honoured place in the treatment of the psychoses, particularly the depressions, despite competition from the psychic energisers.

The instrument, however, which promises to alter the entire face of British psychiatry is not a surgical, but a legal one. The Mental Health Bill (1959) has received the Royal Assent: the substantial changes in the law which it contains should begin to come into operation this summer. The new Bill is indeed a "Bill of Rights" for the mentally ill. It envisages the elimination of the time-honoured practice of treating the mentally sick as second-class invalids. Thus, in future, there will be no "designated hospitals": any kind of hospital may receive any type of mental patient whether on an informal basis or under detention. Furthermore, the emphasis is to be on prophylactic and/or domiciliary services so as to avoid admission to hospital of any sort. For those who do not need, or no longer need, in-patient care the local authority is obliged to set up all types of community care including day or residential training centres, residential accommodation in private homes or hostels, and general and social help and advice.

If the Brave New World for the mentally sick which Britain's legislators have designed is really built—and it is a momentous undertaking—then psychiatry, or perhaps to be more exact, social psychiatry in England, will have hoisted itself to a position of the first rank compared not only with America but with all countries of the civilised world.

MOTOR FUNCTION IN MENTATION ; IMAGERY AND HALLUCINATION ; THE INDEPENDENCE OF THE HIGHEST CEREBRAL CENTERS

MAX LEVIN¹

Liddell, in his thought-provoking work with sheep and goats, made an observation that sheds light on the neural processes of imagery. A metronome ticking once a second is a conditioned stimulus, a mild electric shock being given to the right foreleg on the eleventh tick. When the reflex is established, the behavior of the animal is as follows.

On the third or fourth tick of the metronome he executes a small, precise flexion of the right foreleg followed by a series of deliberate unhurried flexions of increasing amplitude and vigor. Coinciding with the eleventh beat of the metronome a brief electrical stimulus is delivered to the rhythmically flexing foreleg. In response to this electrical startle stimulus (he) executes a brief but vehement flexion of the foreleg reminding one of the withdrawal of the hand at the bite of an insect. Following this rapid, perfunctory flexion (he) immediately resumes his quiet, alert pose.

Liddell accepts Nolan Lewis' interpretation of this behavior, namely that the animal is "symbolically running away with his right foreleg only" (8).

While I have great respect for both Liddell and Lewis I submit that this interpretation is incorrect. In the first place locomotion with one leg in an animal with 4 good legs is inconceivable. In the second place the movements of locomotion, even if only symbolic, would not be "deliberate and unhurried"; they would be rapid. I suggest instead that the rhythmic flexion of the leg is the external sign of *anticipation*.

Having been conditioned, the animal recognizes the first tick of the metronome as the forerunner of a shock. Whatever he may have been thinking before stimulation, the first tick starts the process of anticipation. On the third or fourth tick the rhythmic flexion begins, increasing in amplitude with each tick, the animal knowing that each

tick brings the dreaded shock that much closer. The rhythmic flexion is a sign that he is thinking of the coming shock.

But why doesn't the animal think of the coming shock motionlessly? Why isn't he motionless for the first 10 ticks (which are not accompanied by shock), flexing the foreleg only on the eleventh, in response to the actual shock? He clearly is thinking of the shock before he gets it, and his thinking is associated with flexion of the leg, *i.e.*, with explicit, not implicit, movement.

If the animal could speak, he no doubt would say to himself, "Here is that infernal metronome again. A shock is coming soon. A shock makes me withdraw my foreleg." The image of the coming shock is accompanied by explicit rather than implicit movement because *implicit movement presupposes a more advanced brain than the animal possesses*. Implicit movement is a sign of high evolution.

An illuminating incident occurred in the case of a healthy infant who automatically responded to an aeroplane passing overhead by looking up at it and reaching for it. He also reached for it when he was indoors and heard a plane which he could not see. The incident occurred when he was 12 months old, not yet able to stand unsupported. He was standing at the bookshelf, holding on with one hand, while with the other he was tossing a pile of magazines one by one to the floor, a favorite pastime of his. Presently he heard a plane outside. Still holding on with the one hand, he reached aloft with the other, maintaining this posture until the plane had passed out of earshot, when he resumed his play with the magazines. His image of a plane included a motor component: one reaches up for it.

This lad grew up to become a jet pilot in the United States Air Force. Though he no longer reaches up to try to touch a plane in the sky, I venture to think that whenever he sees or hears a plane, or even thinks of one, action currents still race down

¹ From the Department of Neurology and Neurosurgery, The New York Medical College, Flower and Fifth Avenue Hospitals, New York, N. Y.

the nerves to his shoulder muscles. But there no longer is overt or explicit movement, just implicit movement.

SPEECH

The distinction between explicit and implicit movement is clearly seen in speech, which is the most special and most complex movement of all. Implicit speech is inaudible; it is what we say to ourselves when we think silently. Primitive speech, as in the child learning to talk, is explicit, audible. The child says what he thinks. Enigmatic behavior, the ability to think without tipping one's hand, to keep one's thoughts to oneself, is a trait of the adult, or of the child who has reached an advanced stage of development.

Brain(1) has told us of the little girl who, when admonished to think before she speaks, protested, "But how can I know what I think till I hear what I say?" There is profound truth in her protest. Mentation is interwoven with movement (including speech), which, in early life, is explicit.

Why is it necessary to reach a certain stage of development before one can think without moving (or speaking)? It would seem that the highest cerebral centers must mature up to a point before they can function of themselves, without associated activity of lower centers. The highest centers are newer than lower centers. They are more complex and take longer to develop. At first they seem to "require the support" of lower centers, using them as a crutch. Only after a certain measure of growth and exercise can they dispense with the crutch and function independently, permitting mentation to take place, when necessary, without explicit movement (or speech).

Even at this later stage of development, when we can think without moving (or speaking), there is rudimentary movement, as in the action currents which I have assumed in the case of the man who as an infant reached up for the planes. Golla(3) recorded the movements of his own larynx, and found that when he sang an octave he obtained an ascending curve. When he merely thought of the octave he obtained a similar curve, but of smaller amplitude.

Since thought is so closely interwoven

with speech, it is understandable why some schizophrenics localize their auditory hallucinations in the throat, larynx and mouth. A schizophrenic with *Gedankenlautwerden*, whose case was reported elsewhere (6), said he was "loud-minded," by which he meant his thoughts were "loud," i.e., audible to other people. He said:

Whatever I think, you can hear, without me saying it with my tongue . . . Whatever I think, my voice-box goes like. I should think with my *head*, not my voice-box. [An example?] The other day I was wondering how my blood test was going to turn out, and I heard these words, "I wonder how my blood test is going to be." My lips didn't say it, my voice-box said it. I think in my voice-box, and then it goes up in my mind, and then it sounds just like—(gropes for a phrase)—transformed broadcasts . . . If I was natural (i.e., well), when I think of something, I'd think just a little bit. *This* way, I must think with my voice-box. I must *talk* it, but not with my tongue. It's all in my head.

Another schizophrenic heard voices which came in through his nose and mouth rather than his ears. When asked to explain this, he expostulated, "Your mind is connected with your *mouth*, isn't it?"

In thinking, we use not only the larynx and other organs of articulation, but, since words can be written, we also use our hands. In an article in a literary magazine Malcolm Cowley(2) provides some fascinating material on the physical aspects of the writer's craft. Most writers, he says, "are manual types. Words are not merely sounds for them, but magical designs that their hands make on paper." He quotes Simenon: "I am an artisan. I would like to carve my novel in a piece of wood." Cowley says further:

Hemingway used to have the feeling that his fingers, as they held a pencil, did much of his thinking for him. After an automobile accident in Montana, when the doctors said he might lose the use of his right arm, he was afraid he would have to stop writing. Thurber used to have the sense of thinking with his fingers on the keyboard of a typewriter. When he and Elliot Nugent were working together on their play "The Male Animal" Nugent would say to him, "Well, Thurber, we've got our problem, we've got all these people in the living room. What are we going to do with

them?" Thurber would answer that he didn't know and couldn't tell him till he'd sat down at the typewriter and found out.

Motor function plays an outstanding role in *reasoning*. If we were shown two photographs of a man, one made while he is listening to music, the other while he is doing a hard problem in mathematics, it would be easy to tell which is which. When listening to music a man's face is smooth and relaxed, but when he is doing mental "work" his brow is creased and furrowed.

There is motor activity even when one passively hears a sound. This matter is best understood in the light of Hughlings Jackson's formulations of the neural basis of imagery, which have been quoted elsewhere(5). But, speaking relatively, listening to music is a passive exercise, while problem solving is an active exercise. Problem solving is work—not only mental work but also muscular work as seen in the furrowed brow. What underlies this distinction between passive listening to music and the active solving of problems?

The answer is that reasoning and problem solving involve the manipulation of objects, if only implicitly. The prototype of reasoning is seen in Koehler's chimpanzee. Outside the cage there was a banana and two bamboo sticks, neither of them long enough to reach the fruit, which lay beyond reach. One day the animal fitted one stick into the other and now had an instrument long enough to reach the banana. Between this primitive reasoning and the reasoning of the chess player the difference is in degree only. The chess player may work out a problem without moving a muscle—he may be sitting as still as a statue—but there is movement just the same, implicit movement. There is what Jackson called an "idea of a movement"(4).

In these remarks on the independence of the highest cerebral centers I am merely repeating what Jackson said many years ago. In his paper "On Post-epileptic States," in Section VI, headed "On Degrees of Detachment and Degrees of Independence of Levels of Evolution," he wrote:

Another way of regrading the evolutionary process is to say that the several levels, in spite of their dependence on one another,

attain, as evolution progresses, a degree of independence of one another.

As evolution progresses the highest centres not only gradually develop (become increasingly complex, etc.), but also become more and more detached from, and more independent of, the lower centres out of which they have been evolved . . . There are degrees of detachment and of independence. . . Our highest sensory and highest motor centres (together the "organ of mind") can energise, to a large degree, independently of the lower centres out of which they have been evolved, and by aid of which they have been developed; consequently they can act independently of the environment . . .

The adult, who can think without speaking, may regress to the earlier stage. In some abnormal mental states the patient thinks out loud. On any busy street one comes across self-absorbed people, apparently demented, muttering to themselves out loud. A school teacher emerged from a catatonic stupor and became for a time very nearly normal. She recalled that during the first 4 days of her emergence she felt "horrible," because "I had no speech control. It seemed as if I couldn't *think* things but could only *say* them. There was a great fear in my mind that I would never again be able to think without speaking, and I thought how horrible it would be to have to go through life that way."

IMAGERY AND HALLUCINATION

Thus far our attention has been on movement, a motor function. In sensory function too we must consider the independence of the highest cerebral centers. Here we come upon the function of imagery and the pathological state, hallucination. There must be a reason why a patient has thought echo, or *Gedankenlautwerden*, in which he hears voices that repeat verbatim the thoughts in his mind.

Hughlings Jackson, with his characteristic insight, has given us a lucid formulation of the neural basis of imagery. He said:

I suppose that I am seeing a brick . . . What first happens is that there is a peripheral impression (upon the retina), impulses then pass through the lowest, through the middle, and up to the highest sensory centres . . . So far we have only stated one half of the

reflex action, have only reached the physical condition correlative with the colour of the brick. It and all other objects have shape, and this as much requires to be accounted for as the colour. The shape of an object is the relation of its several positions one to another; our knowledge of this relation is by movements, in this case ocular movements . . . By currents passing from the highest sensory centres, so to speak, "across" to the highest motor centres, and from these downwards, through middle and lowest motor centres to muscular periphery, there is development of movements of the eyeballs . . . Here we have . . . reflex action.

Jackson then considered what happens when we merely think of an object?

The vivid image, the mental state we have (when we see a brick) arises during (not from) the physical condition in the two divisions of the highest centres, and is strongly and definitely "projected," because the lower centres are engaged; it *seems* part of the outer world. Next day, we can think of the brick in its absence, have "an idea of it," or, as I prefer to say, have a faint image where yesterday we had a vivid image. In this case the reflex action is incomplete and weak; the lowest and the middle sensory centres and the middle and lowest motor are not engaged. The highest sensory and motor centres are alone engaged; there is still reflex action, but only the central links of the great sensorimotor chain are engaged; the central part only of the whole process which occurred in perception is done over again, and, the excitations being slight, the image arising is faint, and, the lower centres not being engaged, it is feebly and indefinitely projected, seems more part of ourselves.

Thus Jackson held that during both vivid and faint imagery there is reflex action. Reflex action characterizes the highest cerebral centers no less than the centers in the cord (7). But this does not concern us here. What does concern us is that a vivid image implicates all levels of the nervous system while a faint image implicates only the highest.

There is a correspondence between vivid and faint imagery on the one hand and explicit and implicit movement on the other. In vivid imagery and in explicit movement there is activity of all levels

of the nervous system, lowest as well as highest, while in faint imagery and in implicit movement activity is confined to the highest centers (except for rudimentary activity at lower levels).

We have already seen, in the sphere of movement, that the undeveloped brain does not permit mentation without explicit movement. At any rate, explicit movement seems to facilitate mentation: the child thinks out loud and the infant reaches for the plane. The same holds true *mutatis mutandis* in the sphere of imagery. In the young child vivid imagery accompanies mentation, may even be indispensable to it.

In the study of imagery and mentation we must guard against a romantic misconception in regard to the imagination of the child. It is often said that children have a "rich imagination," more so than their elders. Support for this view is seen in the fact that a small boy will float a block of wood in a puddle of water and call it a boat. But this view is based on a misunderstanding of what imagination really is. Imagination is the ability to see without the eyes, to see through a brick wall. It is the ability to picture an event in advance, to foresee a consequence. A woman with good imagination can look at a hat and know whether it will suit her; one with poor imagination must put it on her head and study the result in the mirror. Since imagination is so complex a function, it is naïve to suppose that children surpass adults in its exercise. This would be like saying that they surpass adults in mathematics. In point of fact they have a *weak* imagination.

Every parent is familiar with the following evidence. The child has a favorite story which he loves to have you read to him. He can hear it a dozen times a day without tiring of it. He has heard it so many times that he knows it by heart, and if you should omit a word or if in a series of adjectives you should transpose the order of words, he will sharply correct you. Why then, since he knows the story by heart word for word, does he want you to read it to him? It is because he cannot enjoy it without hearing it. He cannot *think* it unless he *hears* it. The adult, with his greater imaginative power, can think a thing even when he

does not hear it. He can visualize without having to see.

The bearing of this matter on hallucination has been considered elsewhere(7). The psychotic patient hallucinates because of a deficiency in the power to think abstractly. He has regressed. Here again we must beware of pitfalls in the popular use of the word "imagination." People say the patient *imagines* he hears voices and are apt to suppose that he imagines more than he should, that his faculty of imagination is overactive. In reality his power of imagination is diminished; he thinks in vivid images in circumstances that call for faint images.

In patients recovering from toxic delirium there is significance in the order in which symptoms disappear. While in some cases the symptoms seem to clear up simultaneously, in others they clear up in a certain order. Specifically, disorientation clears up first, while hallucinations persist for some days or weeks longer. Why does disorientation clear up *before* hallucinosis rather than after? There can be only one answer. Orientation is a relatively simple function, while the ability to think abstractly, to think without hallucinating, is more complex. We see this in the 3-year-old child, who is oriented—he can answer such questions as "Whose house is this? Who is this man?"—at an age when he still begs you to read him his favorite story though he knows it by heart.

Jackson had the useful habit of comparing phenomena different in their externals

and discovering that they illustrate a common physiological principle. He insisted on studying the nervous system from the evolutionary standpoint. It's only from this standpoint that we can understand the existence of a common principle in the motor response of Liddell's goat to the tick of the metronome; the child's wish to hear his story read to him; and the hallucinations of the psychotic adult—the principle that the highest cerebral centers, as they mature and advance, gain the ability to function independently of lower centers, an ability which they may lose from disease.

One hundred years from the publication of Darwin's book and nearly 50 years from Jackson's death, it is fitting to pay tribute to these men for having laid the basis for a proper understanding of brain and mind.

THE USE OF RAUWOLFIA FOR THE TREATMENT OF PSYCHOSES BY NIGERIAN NATIVE DOCTORS

RAYMOND PRINCE, M.D.¹

It is well known that *Rauwolfia serpentina* or "snake root" has been employed by the traditional medical practitioners of India for the treatment of psychiatric disturbances for many centuries. It was introduced into Western medicine as a treatment for hypertension about 1949(1), and subsequently as a treatment for mental illness in 1954(2). It is not so well known that *Rauwolfia* has been used extensively by the native practitioners of West Africa as well, and probably also for many centuries.

During a recent tour of duty as a government psychiatrist for the Western Region of Nigeria (1957-1959) I found that while European medicine was highly regarded for the treatment of physical disease, the Nigerian almost invariably preferred to consult the native doctor for psychiatric illness. Almost all the patients attending the psychiatric clinic at Aro Hospital, Abeokuta had been previously treated by one or more native doctors. These included highly westernized patients who were aware that European psychiatric help was available. I had at first thought that the reason for the native doctors' prestige in the field of psychiatry was because of his intimate knowledge of the cultural milieu. Subsequent discoveries however, supplied another, or at least an additional, reason.

Patients attending the clinic frequently described the treatment given to them by native doctors. In addition to such magical practices as the smearing of the body with black soap to prevent being eaten by witches, and the incising of scalp and wrists to ward off malevolent utterances, they often mentioned that they were given potions that were very effective in putting them to sleep. Some mentioned that they had feelings of warmth in their hands and feet after taking the medicine; others described spasms of the neck muscles that pulled their heads to one side and caused their tongues to pro-

trude. Many of the patients who came to the clinic soon after having attended a native doctor showed extra-pyramidal signs—mask-like facies, loss of associated movements, excessive salivation, etc. It was clear that the native doctors were using drugs with very potent biological activity.

In order to explore this problem further I paid several visits to native doctors in the Abeokuta area. On a number of occasions I was shown patients who appeared to be in a profound sleep which had been induced by a "medicine made from a plant." The patient was said to sleep for up to 24 hours following ingestion of the potion. Finally I had the opportunity to spend two weeks in the home of one of the more famous native doctors, Chief Jimo Adetona of Okun-owa. He is a vigorous octogenarian who lives in a three-storied mud house with his 8 wives. He and his forefathers for 5 generations have been specialists in the treatment of mental illness.

His most important medicine² was a bitter, brownish liquid which he gave to almost all his patients. About 6 a.m. each patient was given a half glassful of this liquid; this was repeated at bedtime if the patient complained of insomnia. This medicine was prepared from the root of a tree. Lime juice was added to "make it stronger," (probably the effect was due to ascorbic acid which would prevent the oxidation of the active ingredients).

I was able to obtain a specimen of the tree used and with the help of William Stern of the British Museum in London identified it as *Rauwolfia vomitoria*, Afz.

I do not know how common the use of *R. vomitoria* is among the native practitioners of West Africa but I suspect it is very widespread. Such information is difficult to obtain because native medicines are jealously guarded family secrets and native doctors do not generally discuss their more important therapies among themselves. Dalziel

¹ Formerly Medical Officer (Psychiatrist), Aro Hospital, Abeokuta, now lecturer, Dept. of Psychiatry, Allan Memorial Institute, Montreal, Que.

² Other details of his treatment facilities and methods have been given elsewhere(3, 4).

(5), writing in 1937 describes the use of *R. Vomitoria* in West Africa as follows :

... The root bark has bitter properties and is a drug capable of drastic purgative and emetic effect if used carelessly. It is given for jaundice and other gastro-intestinal symptoms and in the Gold Coast it is applied in the form of an enema mixed with spices. In Nigeria it is given for convulsions in children. A decoction of the root can be used as a sedative for maniacal symptoms, inducing several hours sleep (Dr. O. Sapara). On the other hand the root of the same tree is recorded as in use as an aphrodisiac, taken macerated along with Guinea grains in gin.

It is interesting that in 1925, long before tranquillizers or shock therapies were known to European psychiatry, Chief Adetona, with his *Rauwolfia* medicine, travelled to England to treat an eminent Nigerian who had become psychotic there.

To return for a moment to some of the side effects noted above. Patients attributed the muscular spasms resulting in the pulling of the head to one side or backwards and the protrusion of the tongue to the effects of the native doctors' medicine, i.e. *Rauwolfia*. It is possible that these symptoms were due to *Rauwolfia* intoxication. Toxic effects of this nature have been described with prochlorperazine (Compazine, Stemetil) and chlorpromazine (Largactil). Paulson(6) notes tongue protrusion, tightness of muscles of tongue and throat, and bizarre posturing of the head and neck as being occasional toxic effects of these drugs. I am not aware of reports of such symptoms with *Rauwolfia* or Serpasil. The native doctor was uncertain or at least unwilling to say whether these symptoms were due to his medicine or to some other cause. At any rate he supplied me with medicines to put on the tongue and rub into the neck to prevent them. It is possible that with the poorly controlled dosages of *Rauwolfia*, intoxications would be more common with native treatment or possibly some of the alkaloids present in *R. Vomitoria* but not in *R. Serpentina* are responsible for these symptoms(7).

It is clear however, that the tongue and neck symptoms could occur apart from the

ingestion of *Rauwolfia*. Three cases of neck twisting, tongue protrusion, and the biting off of the tongue with fatal termination have been described(4). In addition, several other cases of spasms of the neck muscles with or without tongue protrusion and not associated with *Rauwolfia* were noted. It is interesting that such symptoms were not uncommon in Europe in the 17th and 18th centuries often associated with the ideas of witchcraft and devil possession. To cite two examples from Robbins(8) *Encyclopedia of Witchcraft and Demonology*, one Elisabeth Allier "possessed by two devils" was exorcised by a church father. The more pressure he put on the devils, the more was Sister Elisabeth seized with strange convulsions—her tongue twisted out of her mouth to the extent "of more than four fingers." A second example is that of one Thomas Darling who accused an old woman of bewitching him. One day he had 27 fits within 6 hours, "shrieking pitifully, blearing out the tongue, his neck so wrythen (twisted) that his face seemed to stand backwards."

It would appear that in western Europe since medieval times, not only has the attitude to mental illness undergone many changes, and the theories of causation, but the patterns of the illnesses themselves. It is possible that there is some similarity between the contemporary witch-ridden Nigerian cultures and the late Medieval European Culture . . . similarities in the level of personality development, patterns of belief and patterns of psychiatric illness. The question might also be raised as to the extent that toxic effects of a drug may be determined by the patient's individual or cultural fears, wishes or symbols in addition to his individual physiology.

CLINICAL NOTES

TRANLYCYPROMINE IN DEPRESSION : A CLINICAL REPORT

HENRY V. AGIN, M.D.¹

Tranlycypromine (trans-dl-2-phenylcyclopropylamine) is a non-hydrazine monoamine oxidase inhibitor, one of a series of new drugs being investigated in the treatment of depression. During a 9-month period, I used tranlycypromine in the treatment of 34 men and 10 women (average age: 46 years—range: 20 to 71 years) with a variety of mild to moderately severe depressive states. The diagnoses were: reactive depression, 27; involuntional depression, 10; manic-depressive depressed, 6; cyclothymic depression, 3; and obsessive compulsive with depression, 2. Presenting symptoms included: indecision, anxiety, inability to concentrate, loss of interests, increased irritability, insomnia, anorexia, various vague somatic complaints, feelings of guilt and unworthiness, pessimism, compulsive and gloomy thinking, emotional instability, and suicidal tendencies.

To reduce the effect of spontaneous remission or placebo reaction, I excluded from the study patients whose depression seemed to be the result of an acute personal crisis. In addition, only patients who had failed to respond satisfactorily to previous treatment with drugs or psychotherapy, or who had responded only to electroshock therapy during previous episodes, and in whom the current episode had persisted for at least 3 months, were included.

Most patients in this series received initial doses of 40-50 mg. of tranlycypromine a day, in divided doses (range: 30-60 mg.). This dosage was usually reduced by 10 mg. after 5 to 7 days of treatment, and further reductions of 10 mg. were made at weekly intervals until the patient was receiving 30 mg. or less a day. Treatment was usually continued for 2 to 3 months (average: 10 weeks). Non-analytic psychotherapy was continued throughout the evaluation for all patients; 6 patients received tranquil-

izers, and 4 EST, in addition to tranlycypromine.

Alkaline phosphatase, cephalin flocculation, and/or serum glutamic oxalacetic transaminase tests were made in 28 patients both before and during treatment with tranlycypromine. In addition, blood pressure readings were taken at each visit, and patients were questioned about the occurrence of other side effects.

RESULTS

The patient's improvement was rated in terms of his ability to resume a normal (for him) level of activity and efficiency. The response of patients who experienced a complete or nearly complete return to "normal" was considered *Satisfactory*; equivocal change or failure to improve was called *Unsatisfactory*. By these criteria, results were *Satisfactory* in 34 (77%) patients, and *Unsatisfactory* in 10 (23%).

In the patients who responded to therapy, some lessening of the severity of symptoms seemed evident within 72 hours, and optimal improvement occurred within 10 to 14 days. There seemed to be no one symptom that disappeared dramatically, no sudden resolution of doubt or worry. Instead, a more subtle diminution of all or most symptoms seemed to occur which was reflected in the patient's behavior, often before he was aware of the change. However, when the patient recognized the improvement that was taking place, his participation in psychotherapy increased markedly, and subsequent improvement was rapid. The overall response of these patients was marked by elevation of mood, increased alertness, disappearance of apathy and confusion, increased optimism, recovery of satisfaction and enjoyment in work and social relationships, and a return of appetite.

¹ 77 Eastern Parkway, Brooklyn, N. Y.

SIDE EFFECTS

Eight different side effects were reported by 17 patients. They included: headache, reported 11 times; insomnia, and dizziness, 7 times each; constipation and drowsiness, 2 times each; and leg cramps, nausea, and anorexia, each reported once. These effects usually occurred at doses in excess of 40 mg. a day, and were controlled by reducing the dosage of the drug. Liver function tests values remained normal throughout the evaluation. There were some fluctuations of diastolic and/or systolic blood pressure, but I could find no correlation between these changes and the side effects reported.

COMMENT

It is difficult to explain why a drug should

be effective in some patients and ineffective in others with the same disorder. An examination of the case histories of the 10 patients in whom results of treatment were *Unsatisfactory* suggested one common factor of possible significance. In each patient, although diagnoses and symptoms varied, anxiety or agitation was a relatively important component of the overall symptom complex. It is possible, that the existence of strong symptoms of anxiety in a depressed patient seriously limits the beneficial effect of this drug. This possibility is weakened, of course, by the fact that some of the patients who improved also exhibited symptoms of anxiety, although, in my opinion, to a lesser degree.

MEMORY CHANGES WITH MAO INHIBITOR THERAPY

• LEON D. HANKOFF, M.D., AND BORIS HELLER, M.D.¹

The side effects seen with pharmacological treatment are generally regarded as troublesome artifacts which may interfere with treatment. Side effects, however, may sometimes provide us with valuable clues as to the pharmacology of a drug. Of particular interest have been the side effects giving evidence of neurophysiological activity, e.g., convulsions and extrapyramidal symptoms with phenothiazine treatment. Fink, in formulating a neurophysiologic-adaptive theory of somatic therapy, has emphasized the occurrence of neurologic side effects with those agents showing greatest clinical efficacy in the psychoses. In the present report, observations have been made regarding an apparently benign side effect occurring with monoamine oxidase (MAO) inhibitor therapy. This is a defect in recent

memory; and it may provide a clue as to the nature of the altered brain functioning associated with the antidepressant activity of the MAO inhibitors.

Approximately 100 ambulatory depressed patients were treated in the Mental Health Clinic, Kings County Hospital Medical Center, with isocarboxazid. The usual treatment course was 10 mg. t.i.d. for 8 weeks. The patients were seen at weekly intervals in brief followup interviews after an initial workup. During the course of the study, several patients complained of recent memory loss; and, as a consequence, an inquiry into memory functioning was made part of the followup interview routine. To date, 8 patients have presented the complaint of recent memory loss. All 8 patients claimed to have had normal memory before using the medication and on intake psychiatric interview there had been no evidence of organic brain disease. The age range was from 24 to 59 with a mean of 43.1 years.

The complaint of memory difficulties usually began after two to three weeks of drug treatment and cleared up within a week of drug discontinuation. The patients complained that they forgot details of recent

¹ From the Department of Psychiatry, State University of New York, Downstate Medical Center, Brooklyn, N. Y. The study was undertaken by the Psychopharmacological Research Unit of the Downstate Medical Center under the direction of David M. Engelhardt, M.D. It was supported in part by a grant from Hoffmann-La Roche Inc. to the Research Foundation of the State University of New York. The isocarboxazid used was supplied as Marplan by Hoffmann-La Roche Inc.

events, misplaced things, or failed to attend to minor chores. A frequent comment was that the patient could not remember whether he had taken the latest dose of his medication. Several mentioned that they had forgotten to pay for items taken from store counters; and one suggested that his attention span for such details seemed narrower. In contrast, memory for distant events was unimpaired. Seven of the 8 patients showed a considerable degree of clinical improvement, generally seen at about 3 weeks of drug treatment, that is, somewhat later than the memory impairment onset.

Our findings suggest that altered brain functioning of clinical significance may accompany MAO inhibitor therapy. It may be that this altered brain functioning is related to the phenomenon of clinical improvement

associated with this therapy in depressive illness. It is well known that impairment in memory accompanies electroshock treatment; and some correlations between the degree of altered brain functioning and clinical response have been made for the electroshock process. It should be noted, however, that only a small fraction of our patients manifested a clinical degree of memory impairment and that the vast majority of clinical improvements we observed were unaccompanied by this side effect. We are presently engaged in a systematic investigation of memory impairment in isocarboxazid therapy. The possibility that some particular aspect of recent memory functioning, *e.g.*, recall or attention span, may be differentially affected is being studied through psychometric testing.

PERSISTENT MUSCULAR RESTLESSNESS AFTER PHENOTHIAZINE TREATMENT: REPORT OF 3 CASES

WALTER KRUSE, M.D.¹

Case 1.—This is a 55-year-old female patient diagnosed as paranoid schizophrenia. In 1957 she was treated for many months with chlorpromazine up to 1,600 mg. daily. In April 1958, trifluoperazine was given up to 90 mg. daily. After 2 months of this high dosage there was a very remarkable improvement of her mental condition. Trifluoperazine was then slowly decreased. In December 1958 when she was on 20 mg. daily our patient developed an increasing muscular restlessness largely but not completely confined to the legs. This restlessness subsided at night when patient went to bed, but it was very annoying all day long. There were also occasional jerky, involuntary movements of both arms and involuntary lip and tongue movements. (Except for minimal facial fixity and slight salivation there had been no Parkinsonian symptoms in this patient before the rather sudden appearance of the akathisia-like syndrome.) Trifluoperazine was now gradually withdrawn, the usual antiparkinson drugs were given, phenobarbital up to 300 mg. daily was also tried—but all this was of little or no benefit. Our patient still cannot keep her legs still—after 18 months—but the recently started treatment with 75 mg. of

methaminodiazepoxide (Librium) daily has helped considerably to control the involuntary movements.

Case 2.—A 58-year-old schizophrenic woman who was treated with 20 mg. of fluphenazine and 300 mg. of trifluoperazine daily developed an akathisia syndrome which consisted of inability to sit still, pacing the floor all day, jerky movements of arms and shoulders. When the addition of 2 antiparkinson drugs showed no result the phenothiazines were withdrawn. Three months later the patient still is restless, cannot sit still and shows infrequent involuntary movements of both arms, but there is some improvement.

Case 3.—This is a 50-year-old paranoid schizophrenic woman who has been ill for a long time but who was only recently admitted to this hospital. She began to show restlessness of her legs when she was on 400 mg. daily of thioridazine. Here again the usual antiparkinson drugs were without effect. Thioridazine was discontinued after a month during which the restlessness had increased in severity. She was then given 40 mg. daily of methaminodiazepoxide and again there was considerable

¹ Danvers State Hospital, Hathorne, Mass.

but not yet complete relief from the annoying involuntary leg movements and the distressing feeling of muscular restlessness.

DISCUSSION

While it is true that the drug-induced extrapyramidal symptoms usually disappear within a few days after the drug is discontinued we have now seen 3 cases (among more than 2,000 patients that have been treated with various phenothiazines over long periods) where these symptoms persisted for 3-18 months after the drug was

stopped. The question arises whether phenothiazines are always as innocuous as we had believed them to be.

In the three cases reported here one might speculate that the phenothiazines precipitated the development of an extrapyramidal syndrome in patients that were already predisposed for it. The fact that all three patients were 50 years or older might suggest the presence of vascular changes in the extrapyramidal system as the organic basis for such a predisposition.

ON THE MEASUREMENT OF ADRENOCHROME IN BLOOD

AXEL RANDRUP, Ph.D., AND IB MUNKVAD, M.D.¹

The fluorimetric method used by Hoffer *et al.* (1) for the determination of adrenochrome (or closely related substances) in blood has been the subject of some controversy (2, 3, 4, 5, 6, 7, 8). Recently a detailed description of the procedure was published by Payza and Mahon (6), and following this procedure we have obtained experimental data which may be pertinent. The data² are open to interpretation, but our own conclusion is that because of the high blind values, reliable measurement with this method is not possible.

The experiments were made with meticulous care and the published procedure followed in every detail, the only exception being the separation of the protein, which we carried out by centrifugation at 3,500 r.p.m. in a swingout centrifuge head. This relatively slow centrifugation may be the cause of a slight turbidity which was in some cases observed in the plasma blank. To control the possible effect of this turbidity upon the measurements of fluorescence, we made in 14 experiments simultaneous measurements of two or four parallel plasma blanks; in some of these experiments one plasma blank was clear and another turbid, in others there was difference in the degree of turbidity, but in no case could we observe any difference in the

fluorescence. Clear plasma blanks could be obtained by filtration, but even the purest filter papers gave off a little fluorescent material, enough to have serious influence on the accuracy of the measurements. We therefore preferred the centrifugation. The tube with reagents incl. Zn also was slightly turbid in some cases, but also here we could ascertain that the turbidity did not influence the fluorescence. The measurements were made with an Aminco-Bowman spectrofluorometer, which also permitted observation of the activation and fluorescence spectra. The fluorescence spectra of the plasma extracts with and without Zn were similar to those published by Payza and Mahon (6), but also the reagents alone (with and without Zn) gave spectra of similar shape.

THE EPINEPHRINE-MECHOLYL TEST APPLIED TO A STATE HOSPITAL POPULATION

PANDELIS K. PANDELIDIS, M.D., AND ROBERT D. BUSIEK, M.D.¹

The epinephrine-mecholyl test (Funkenstein Test)(1) has been used as a means to determine prognosis and to guide treatment in mentally ill patients. This has been done largely with private patients or on hospital services admitting a select group of patients. The concern of the present study² is the application of the test to the somewhat different population admitted to a large state mental hospital. Here, such factors as age, chronicity of disease and socio-economic background tend to give an unfavorable prognosis as judged by ordinary clinical methods. Comparison of this expectation with test results and ability of the test to add to clinical judgment in this group were sought.

MATERIAL AND METHODS

One hundred and thirty-two patients were selected at random from new admissions, excluding those who had recent treatment, those with organic psychoses, and most of those with a diagnosis of psychopathic personality. They ranged in age from 16 to 75, with an average age of 39 years. Eighty-eight were female and 44 male. The Funkenstein test was administered by one of us, and utilized 10 mg. of Mecholyl IM with blood pressure and other observations for 30 minutes, followed by 1/20th of a cc. of 1/1,000 epinephrine IV with an observation period of 5 minutes. Treatment was given without reference to the Funkenstein test results. The test results were classified on the basis of Funkenstein's criteria without the modifications used by Alexander(2).

Observations on patients who remained hospitalized were necessarily more complete than on those who left the hospital. Psychiatric and social service evaluation was usually possible for many months on an

outpatient basis, however. The test results were not included in the patients' records during a three-year follow-up period.

For the purposes of this paper, patients were classified as recovered, improved, or unchanged. Discharge from the hospital and maintenance of a social adjustment without the need for intensive therapy was taken as indicating recovery. A classification of improved was made on the basis of adjustment either inside or outside the hospital. The difficulties of this sort of evaluation of psychiatric patients are acknowledged, and they make the results inferential rather than conclusive.

RESULTS AND DISCUSSION

As applied to our patients, the Funkenstein test allowed a classification similar to that reported by others. On clinical grounds, it was expected that a high proportion of our patients would have a relatively unfavorable prognosis. With roughly 50% in the favorable and 50% in the unfavorable groups, this assumption is given some support. The usefulness of the test in these patients is now to be considered.

Nearly 50% of the patients fell into the group with the highest recovery rate. Most of the patients in this group received ECT, some in combination with thorazine. Of these, 64% recovered. Treatment in this group with drugs alone or psychotherapy was less successful. This favorable effect of ECT is to be contrasted with results of convulsive treatments in other groups where approximately 50% received ECT with a recovery rate averaging 24%. This is suggestive that ECT was the treatment of choice in the high recovery group.

The unfavorable groups comprise a therapeutic problem. Group V was given a very poor prognosis by both Funkenstein and Alexander. The recovery rate appears to be higher in the present series. One explanation may be the use of thorazine, both alone and with ECT. It may be expected that the test groups would provide an indi-

¹ Senior psychiatrist and formerly junior psychiatrist, Taunton State Hospital, Taunton, Mass.

² We wish to acknowledge the assistance and encouragement given in this study by Dr. W. E. Glass, Superintendent, Taunton State Hospital.

cation for the use of drugs as well as for other forms of therapy. Drug therapy in the present series was so limited, however, that this remains conjectural. Alexander's (4) use of non-convulsive electric stimulation to improve the prognosis in certain patients also is an indication that the test may provide a basis for more effective therapy.

It has been stated that the prognostic value of the test exceeds that of clinical diagnosis. While this may be true if diagnosis alone is considered, clinical prognosis is usually based on many other factors also, including heredity, prepsychotic personality, and environmental factors. While the test may provide additional information, it is likely that a final evaluation will necessarily include the traditional considerations also.

SUMMARY AND CONCLUSIONS

The Funkenstein test was given to 132 patients newly admitted to a large state hospital. It was concluded that the test probably is capable of giving valuable prognostic information about such patients. The possibility that it gives an indication of the most effective form of therapy was also raised.

MOOD ELEVATING EFFECTS OF CHLORPHENOXAMINE HCl

DAVID M. EISENBERG, M.D., AND GERALD H. ROZAN, M.D.¹

The method of this study was to give a large dose of chlorphenoxamine HCl² to a group of psychiatric patients with varied diagnoses, but all with a depressed mood, to determine if a primary euphoric effect would be produced.

Doshay³ has indicated that this drug has a mood elevating and energizing effect. It was introduced as a therapeutic agent for paralysis agitans and was found to influence muscular rigidity. It was also noticed that the patients experienced an elevation of

mood. The question was then raised as to whether this euphoric effect was primary or secondary to the alleviation of unpleasant physical symptoms.

Chlorphenoxamine HCl which is similar in chemical structure to diphenhydramine (Benadryl) hydrochloride was always used in the dose of 100 mgms. q.i.d. Twenty-three patients were given the drug for 3 weeks and were evaluated at weekly intervals. Nineteen of the 23 were evaluated as having had an elevation of mood. Of the 5 patients who did not have a beneficial effect, 2 appeared mildly agitated. One stated that he was "more nervous." There were no deleterious side effects. An elevation of mood was seen generally within 3 to 4 days. Further studies seem indicated.

SERUM PROTEIN PARTITION AND NEW DRUG EVALUATION

JOHN R. SHAWVER, M.D., AND STANLEY M. TARNOWSKI, M.S.¹

Recently we participated in a cooperative chemotherapy study supervised by the Central Office of the Veterans Administration, of 20 chronic, quiet schizophrenic patients. During this double blind study all these patients were taking chlorpromazine in daily doses of 200 mg. to 400 mg. and all of them continued to take chlorpromazine in the same dosage throughout the study. In addition these drugs were added: dextro-amphetamine (Dexedrine) 10 mg. to 60 mg. daily was given to 4 patients, isocarboxazid (Marplan) 5 mg. to 30 mg. daily was given to 4 patients, trifluoperazine (Stelazine) 5 mg. to 30 mg. daily was given to 4 patients, imipramine (Tofanil) 37.5 mg. to 225 mg. daily was given to 4 patients, and 4 patients received a placebo. This study extended over a period of 5 months and 18 patients completed the project. The results will be reported later by the Central Office of the Veterans Administration after all reports

from participating hospitals have been received and analyzed.

A sensitive method of measuring hepatic function is the quantitative partition of serum proteins employing electrophoretic technics. This method of detecting hepatic damage was added to the group of tests generally accepted as "liver function portfolio." The serum proteins were estimated at monthly intervals employing a Spinco Unit and procedure B.

In our series of 18 patients, no abnormal findings were observed as measured by this technic. However, false positive results were occasionally observed in cephalin flocculation and thymol turbidity test which could not be duplicated nor were they clinically significant.

CONCLUSION

It is recommended that in evaluating any new drug with regard to possible liver damage, serial estimations of serum proteins by electrophoretic methods be employed.

CLINICAL OBSERVATIONS ON RITALIN¹ HCL
(METHYLPHENIDYLACETATE) INJECTABLE,
MULTIPLE DOSE VIALKURT WITTON, M.D.²

The parenteral use of Ritalin, the cerebral stimulant and antidepressant, is relatively new and has not been evaluated thoroughly. This study of the effects of injectable Ritalin was made on 40 male patients, ranging in age from 26 to 69; 31 were chronic schizophrenics hospitalized for more than 5 years and 9 were depressives (neurotic, involutional and psychotic).

Each patient was given 6 to 10 treatments

at several day intervals within 4 to 6 weeks. A one week observation established pre-treatment blood pressure patterns. Treatment consisted of intravenous injections of 1 cc (10 mg.) per minute; tolerance was established by increasing test doses, starting at 20 mg. Full vial (100 mg.) was excessive; optimal dosage was found to be 5 cc (50 mg.). Each patient was observed from one to several hours, frequent blood pressure checks were made. The physician conducted 40 to 50 minute psychotherapeutic interviews similar to those in narcoanalysis. Since the often impressive "explosive catharsis" sometimes lasted several hours, trained aids continued psychotherapy. Of the 40 patients, 10 also received intramuscular injections of 2 cc of Ritalin

¹ The Ritalin used in this investigation was kindly supplied by Dr. F. J. Vinci, of the Ciba Pharmaceutical Products, Inc., Summit, New Jersey.

² VA Hospital, Fort Meade, S. Dak. The statements and conclusions published by the author is the result of his own study and does not necessarily reflect the opinion or policy of the Veterans Administration.

daily for 10 days; this was continued 2 or 3 times weekly for several weeks.

Each patient served as his own control. Comparative treatments were given with intravenous Desoxyn (methamphetamine, 20 mg.) and sodium amytal (7½ gr. in 10 cc of H₂O). No change showed in the basic pattern of the 10 patients who underwent electroencephalographic studies. No blood dyscrasia or liver damage were observed.

This study shows that injectable Ritalin has greater and more immediate effect than its oral dosage. The main observations were:

The marked cerebral stimulation resulted in an immediate feeling of well being. Frequently "explosive catharsis" produced favorable abreaction with reduced hostility, anxiety and depression. Alertness, concentration, conation, speech, coherence, memory recall were greatly stimulated and improved. Often psychodynamically important repressed material was released, giving new perspectives for treatment. In chronic depressed or apathetic patients this abreaction might be the turning point where continued stimulation and remotivation efforts will result in successful therapy. In several cases of muteness, catatonia, lethargy, an immediate reversal and improvement were obtained.

Side reactions dependent on individual tolerance and sensitivity and possibly related to pressor effects were restlessness, palpitation, dryness of the mouth and exaggerated muscle activity, which subsided within 30 minutes. Headaches were rare, in a few cases insomnia was found. No seizures occurred. Sodium luminal, gr. 2 im. or sodium amytal gr. 3½ im., abolished side reactions quickly. Panic reactions with dyspnea, chest constriction and fear of im-

mediate death occurred in 3 patients of high sensitivity, only when the full (100 mg.) dose was given.

Contrasting opinions in reference to Ritalin's effect on blood pressure range from no essential change to hypotensive and hypertensive effects, the majority reporting moderately increased blood pressure. In this study 22 of the 40 patients had a significant systolic pressure increase averaging 50 points. Of the remaining 18, 10 had increases of from 30 to 50 points. The diastolic pressure increased to 90 or more in 36, in 24 of whom pressures of 100 or over were found. Although caution is recommended in determining optimal dosage, a large safety margin is apparent.

Prolonged intramuscular use on 10 patients had no dramatic effect but seemed to improve chronic depression. Counter effect on lethargy or sedation produced by barbiturates and tranquilizers was confirmed.

Ritalin was found very effective in the treatment of hypotension, particularly orthostatic, following the use of some phenothiazines and anti-depressants. It can be safely given with most phenothiazines. If given preventively in doses of 2 to 4 cc i.v., the parenteral use of phenothiazines such as chlorpromazine and promazine is safer because a dangerous drop of blood pressure to shock level might be prevented. This is particularly recommended in cases of a labile cardiovascular system. Since the content of thought processes becomes overt during treatment, Ritalin has great value in differential diagnosis.

In psychotherapy, compared to the frequent agitation following Desoxyn and the amnesia following sodium amytal, Ritalin favors more lasting improvement in alertness, memory recall, mood and affect.

PRELIMINARY RESULTS WITH FLUPHENAZINE (PROLIXIN) IN CHRONIC PSYCHOTIC PATIENTS

JOHN P. HOLT, M.D., AND ELEANORE R. WRIGHT, M.D.¹

Following a pilot study in which 5 of 6 chronically disturbed patients displayed significant improvement in psychotic behavior after treatment for 3 days with

fluphenazine (Prolixin),² a clinical study was undertaken at this hospital to evaluate the drug in a more extended series of patients with chronic mental disorders. Most

¹ Embreeville State Hospital, Embreeville, Pa.

² Supplied by E. R. Squibb & Sons

of the patients chosen for study were considered to be "management problems"; all were resistant to earlier ataractic therapy. Fluphenazine proved to be a highly potent psychopharmacologic drug with the swiftest onset of action and the longest duration of effect of any other oral ataractic agent yet employed at this hospital. Preliminary findings in the use of this drug are briefly presented below.

METHODS

Thirty-one male and 19 female patients, age range 33 to 78 years, were suffering from chronic psychotic disorders, diagnosed as schizophrenia in 26 patients, manic-depressive reactions in 3, involutional psychotic reaction in 6, and chronic brain syndrome in 15 patients. All of the patients had been hospitalized for at least 3 months, some for as long as 16 years. The average stay in hospital for the group was 4.1 years. Each had received one or more ataractic drugs such as chlorpromazine, trifluoperazine, prochlorperazine and reserpine. Nine of the patients had also received ECT. Though many had improved temporarily, none had shown significant progress for the two months prior to the present study, and several were refractory to all types of drug therapy.

Fluphenazine was administered orally throughout the study either as tablets containing 1 mg. or 2.5 mg. of the drug, or as an elixir containing 5 mg. per cubic centimeter. Initial doses ranged from 1 mg. to 22.5 mg. a day, depending on the severity of symptoms, smaller doses being prescribed for the elderly, or those with asso-

ciated physical illnesses. The dosage was adjusted, as indicated, during regular weekly evaluations of each patient. An effort was made to establish the maximum amount each could tolerate without unwanted effects and the minimum amount that was beneficial. Maintenance doses, given once or twice daily, varied from 1 mg. to 15 mg. a day. Treatment was continued in every case for at least 70 days.

RESULTS

The results of treatment were as follows:

A response to fluphenazine was often apparent within 24 to 48 hours and significant improvement, even in chronic drug-resistant patients, was frequently seen within 3 weeks. Benefit was usually first manifested by the patients becoming less impulsive, more cooperative, and more interested in their surroundings. Delusions, hallucinations and bizarre behavior generally subsided more gradually. Perhaps the most striking feature of therapy was the profound tranquilizing effect of fluphenazine in hyperactive and aggressive patients on the one hand and, on the other, its psychomotor stimulant action in activating passive, inactive, lethargic patients.

Unwanted effects common to other phenothiazines were encountered with fluphenazine such as drowsiness, dry mouth, insomnia, headache, and gastrointestinal complaints. These reactions usually subsided spontaneously or responded to symptomatic measures. The most frequent and bothersome reactions were motor restlessness, dyskinesia and parkinsonism syndrome; these were controlled by anti-park-

Diagnosis	Total No. of Patients	Markedly Improved *	Moderately Improved *	Unimproved *	Total No. Improved
Schizophrenic Reactions	26	3	12	11	15
Manic-Depressive Reactions	3	1	1	1	2
Involutional Psychotic	6	2	3	1	5
Chronic Brain Syndrome	15	1	6	8	7
Totals	50	7	22	21	29

* Marked improvement: complete remission of all objective symptoms and significant relief or subjective symptoms; good candidate for rehabilitation.

Moderate improvement: partial remission of objective and subjective symptoms; patients easier to manage on the ward.

Unimproved: no significant change.

insonism medication and/or a reduction in dosage.

CONCLUSIONS

Fluphenazine is a highly potent psychopharmacologic agent which is effective in controlling behavioral symptoms in chronic psychotic patients with the most pronounced changes manifested in reduced agitation and tension and improved social-

ization; the drug is also effective in controlling hallucinations and delusions. Through greater individualization of dosage may be required with fluphenazine than with other phenothiazines for maximum benefit with minimum reactions, fluphenazine appears to have great potential usefulness in the treatment of chronic psychotic patients.

HISTORICAL NOTES

I REMEMBER STEWART PATON

Among other good reasons there is one especially strong personal one for remembering Stewart Paton, for it was he who directed my steps into the labyrinth of psychiatry, from which, lacking the thread of Ariadne, it has never seemed possible to find the way out.

Of real significance however, is the fact that it was Paton who in his quiet and courtly way initiated the advance movement in psychological medicine at the Johns Hopkins School of Medicine at the turn of the century, exerting an influence that was to be felt far beyond the boundaries of the United States.

Only six years earlier Weir Mitchell had dropped his bombshell among the psychiatrists—alienists they were usually called then—assembled in Philadelphia for their semi-centennial meeting. He chided them for their lack of science and for not conducting their hospitals so as “to keep treatment or scientific product on the front line of medical advance.” It was institutional men that Weir Mitchell was addressing and he upbraided them for the institutional climate that he called “asylum torpor.” He reminded them too, that in treating patients, what it is necessary to deal with “is not a disease, but a disease plus a man.” Herein he felt the asylum men largely failed.

But if psychiatry was backward in the America of the eighteen-nineties so was the teaching of medicine generally. However, during that decade a revolution in medical education was getting under way at the newly established Johns Hopkins School of Medicine in Baltimore, and a pattern was set that was to be followed at other schools throughout the country.

It was the era of “The Four Doctors”—Welch, Osler, Kelly, and Halsted—and the beginning of “The Heroic Age of Medicine” as Simon Flexner called it. Soon there were gathered about the four founders other eminent and preeminent teachers, men “of the highest character and the greatest skill,” as Johns Hopkins had specified in his in-

structions to his trustees. By the time the school opened in 1893 and the first class was launched, the faculty had been expanded to fifteen, and others were soon added. Teaching in all the branches of medicine was being redesigned and broadly amplified, virtually on a graduate level from the start as compared with other schools (the Hopkins was the first medical school in the country to require an A.B. degree or its equivalent for entrance).

In this early group of teachers was Stewart Paton. He gave a new direction and a new impetus to the teaching of psychiatry reflecting the methods of the German clinics. The advanced position of Germany in this department can be illustrated by the fact that Griesinger, while *Privatdozent* in Tübingen, had written the first modernly organized textbook in 1845, while the first comparable American text (Spitzka's *Insanity*) did not appear until 1883. By the turn of the century each of the twenty-odd German universities had a well organized psychiatric clinic and teaching staff and where clinical, pathological, and psychological research was going on.

With all this work Paton had personal knowledge and he set about writing the first modern textbook of psychiatry on the American continent. This 600-page volume was published in 1905 and became at once the standard teaching text. But Paton had in mind something beyond pedagogy. “My main object has been to call attention to that aspect of the subject which is in accord with the results of observations as they are conducted today at the bedside and in the laboratory . . . to stimulate to greater activity the interest in the investigation of problems in the solution of which will be found the means of increasing the brain power of the nation.” (Paton would not allow himself not to be hopeful.)

This book was probably reprinted once without revision as it is listed again in a Lippincott catalogue dated 1912, after which date the publishers report that it

must have been allowed to go out of print. It is a great pity that the author did not bring out new editions to keep his book updated and as a continuing guide among the divergent paths that psychiatry took as the twentieth century advanced.

In the last decade of the nineteenth century there came into existence a new private psychiatric facility in the Baltimore area to which Paton made a major contribution. This was the Sheppard and Enoch Pratt Hospital at suburban Towson, of which Dr. Edward N. Brush was superintendent. Dr. Brush availed himself of the services of Dr. Paton to organize and direct the scientific work of the hospital. Paton was appointed director of the laboratory and he set the pattern for both clinical work and pathological investigation, and for training young medical graduates to become psychiatrists. It was my fortune to be the first of a long line of trainees who in those early years came under Paton's benign and stimulating influence and guidance. When he proposed this post to me he did not omit to mention the desirable living quarters at the hospital, the congenial family life there and especially the excellent staff table, having in mind no doubt the likelihood that impecunious medical students had not always dined sumptuously.

Dr. Paton might almost be called a free-lance social scientist. Having independent means he gave freely of his time and his wisdom wherever and however they would best serve the interests of mental medicine, education, student training and welfare and social health. A fixed position such as that of the head of a university department with routine duties and administrative tasks would hardly have been to his liking. As associate in psychiatry at the Hopkins he could enjoy freedom of action. The students' main contact with him was in the outpatient service where he could instruct them in the neurologic and mental health problems of everyday life.

Paton was, I think, about the sanest psychiatrist I have known, at least I haven't known a saner. He taught that mental disease and mental health are based on the total physiological economy. He harbored no preconceived idea or theory that he must defend. He did not set up a school. He

emphasized constantly the importance of education both in promoting sound living and a healthy mind and in correcting unwholesome trends that predispose to mental breakdown, and that, if recognized and dealt with in time, might be alterable.

While Paton doubtless exerted his greatest influences and made his most important contribution in the huge area in which psychiatry, mental hygiene and education are included, his interests were many, one of the strongest being the embryology and biology of the nervous system. And so it was that after completing his textbook he came back to this subject by spending several years in the marine laboratory at Naples investigating the embryology of the central organs in the material there available.

On returning to the United States in 1910 he settled not in Baltimore but in Princeton, New Jersey, where he lectured at the university on neurobiology. During that period I was attached to the staff of the New Jersey State Hospital at Trenton and as Paton had been appointed a trustee of this hospital I had the advantage of further contacts with him both in Trenton and Princeton.

It was at Princeton that he originated a mental health consultation service for students. This was in 1910, a turning point in university health services. "Until that time," as Paton has told us, "the results of the physical and academic examinations were not brought together so as to give students some connected idea of their physical and mental activities and of what they were psychobiologically fitted to do." Of every student referred or voluntarily seeking advice he made an exhaustive case study. As might have been expected this innovation in university life received the hearty cooperation of "many, but not all, members of the faculty." The high value of what he could offer, however, was obvious when he reported some of his findings, "students who had pronounced suicidal, homicidal impulses, sex perverts, those who stole, cheated, were exceedingly egotistical, aggressive and showed other signs of serious maladjustments."

Having demonstrated the value of mental hygiene counselling for students at Princeton, not alone as an integral part of the health services but also as an important

feature of the educational process, Paton had the opportunity of initiating similar work at Yale and later at Dartmouth and Columbia. The movement has since spread across the country. "I switched from psychiatry to education," Paton had said, "as it seemed to me that unless students and the public were educated in humane ways of living there would be no way of checking the spread of the emotional and mental disturbances that are the greatest existing menace to democratic forms of government and to civilization."

When World War I came to the United States Paton was one of the first Americans to visit Canada, already a veteran of the war, to learn of her experience in dealing with psychiatric war casualties—"shell shock" as they were commonly called, perhaps because of the striking alliteration. Paton's advice was sought in Washington in setting up the psychiatric service in the American army and his recommendation to the Surgeon-General of the appointment of Thomas W. Salmon to organize this service in the A.E.F. and Pierce Bailey for like duty on the home shores was profitably adopted. It should be recorded also that Paton was one of the first to insist on the importance of psychiatric examination of aviators; he was appointed director of the neurological division of the research laboratory established at Mineola at the beginning of World War I.

Stewart Paton was a peaceful man^o but no pacifist. Of World War II he said, "the present plague of insanity is the most contagious, virulent pestilence of which we have any record. To believe that we can remain pacifists, non-interventionists, and isolationists in the present war is a symptom of insanity." He could speak out when the forces of night threatened the daylight of the world.

The establishment of the Henry Phipps Psychiatric Clinic as a part of the Johns Hopkins Hospital represented one of Dr. Paton's major goals. Adolf Meyer, the first director of the Phipps Clinic, said "Without his stimulus William Osler and William H. Welch would hardly have become the sponsors for the donation of Mr. Phipps." And Dr. Welch made the statement that it was

Paton who had helped him to understand the importance of psychiatry in medicine.

When the Phipps Clinic was formally dedicated in 1913, with an impressive international panel of speakers, Paton was appropriately given first place on the program.

Paton's influence in promoting psychiatry was salutary in four universities, at Columbia in supporting the appointment of Dr. Salmon as professor of psychiatry and at Yale in collaborating with Dr. Winternitz, the professor of medicine, in establishing the Institute of Human Relations, and at Johns Hopkins and Princeton as has been noted. He was also a trustee of the Carnegie Institution and of the Josiah Macy Jr. Foundation.

Many honours came to Dr. Paton. In his later years, because of impaired health, he felt it necessary to decline some of those that would have involved considerable responsibility. One that he particularly valued and regretted the inadvisability of accepting, was his choice for the Presidency of the American Neurological Association.

Although he did not keep his textbook in print in new editions he was busy later in writing other books of wider reach in the interests of education and healthy living. One of these, coming shortly after World War I, was *Education in War and Peace* (the Harvey Lecture).

Paton was a fine human being and lessons could be taken from his own exemplary pattern of life. Some of the notable things he did may not be generally remembered because he worked so quietly and unostentatiously. It is desirable therefore to recall that it was he who pioneered in all the forward movements in the United States of his time in the science of human conduct and the promotion of sane living. Among the numerous new lines of work he laid down it would be difficult to select one as being more important than the others. Certainly none has been of greater and more enduring value than his unique contribution in setting up at Princeton University the first mental health clinic in America for students in the higher institutions of learning, a service now widespread throughout the country.

C.B.F.

COMMENTS

1960 CAMPAIGN FOR POLIO PROTECTION

At the request of the United States Public Health Service the National Health Council is cooperating in publicising the urgent need of expanding further the use of the Salk vaccine as a protective measure against polio throughout the nation.

There are still too many needless cases of this crippling disease. In 1959 there was a 54% increase over 1958 of paralytic polio cases. Of these cases, 82% occurred in persons who had not been fully vaccinated. Nearly half of all paralytic cases were pre-school age children. There are still 4,500,000

children under 5 who have received no vaccine.

Remembering that the Salk vaccine proved approximately 90% effective in the prevention of polio in persons fully vaccinated in 1959, any cases in persons who have not been fully protected must be regarded as *needless*. Inertia, complacency and groundless prejudice and fears must be combatted. All local psychiatric and neurological societies are urged to cooperate actively with health authorities in extending the use of the Salk vaccine uniformly throughout their respective communities.

THE SOCIAL PROBLEM OF EPILEPSY IN PERU

Liga Peruana Contra la Epilepsia.—The Peruvian League Against Epilepsy, with headquarters in Lima (President, Dr. Federico Sal y Rosas, General Secretary, Dr. José Sánchez G.), a filial institution to the National League has planned an active program for the next two years in public education, scientific studies, training of students, lectures for general physicians, providing treatment for indigent epileptics and workshops for the employment of needy patients, education of the epileptic child, securing employment in industry for suitable cases, establishing special treatment centers and securing legislation in the interests of epileptic patients. Surely a formidable program, and a wonderful undertaking.

It is estimated that there are 100,000 epileptics in Peru (10:1,000 population), the natives of that country being more susceptible to convulsive disorders than people in temperate climates. In one of the slum areas of Lima a ratio of 56 per 1,000 population was found.

Work of the League is handicapped by prevailing prejudice and superstition. The rank and file regard the convulsive attack with horror, consider the condition contagious and the patient dangerous. It is also

thought that manual or intellectual work aggravates the disease.

There are 3½ million children of school age (5-19) in Peru; of these, 36,000 are epileptic, the great majority of whom would be able to attend school. But they are excluded from the schools because of the prejudice against them. Thus illiteracy is promoted and constitutes a serious problem. Of adult epileptics it was found that only 2% had achieved a higher education.

Among the inhabitants within the age range capable of remunerative work (20 to 69) are 50,000 epileptics who are "universally rejected" by industry although the League estimates that 80% of these would be capable of regular work. "In Peru 72,000 socially able epileptics are unfairly deprived of education and work" and constitute a huge unproductive segment of the population and an economic burden to the country whose economic status is none too secure.

There is as yet "no specialized center of medical service for the treatment of epileptics. The poor epileptics apply to the dispensaries of the Sociedad Beneficencia, among other neuropsychiatric patients, where they are provided only with pheno-

barbital and bromides. Modern antiepileptic medicines cannot be provided due to the high prices, therefore treatment is inadequate. Only a small minority, which we calculate forms 2-3% of the patients, is benefited by modern methods. There are no centers for the study of epilepsy nor stimulus to research."

The President of the League is also seeking to secure legislation which will correct

the unfortunate social and economic status of persons subject to epilepsy and provide for their educational, medical and occupational needs in accordance with modern scientific knowledge of this disability.

In our neighbor country to the south epilepsy is indeed a major public health problem and the Peruvian League deserves great credit for the courageous struggle it is carrying on against heavy odds.

CASE HISTORY

Because "together" is the great central word of human life, no education can be rounded or comprehensive which does not involve a good all-around acquaintance with men and women of all sorts and conditions. Because this is so, biography, if it be well written, is agreeable and attractive. Indeed, a good novel succeeds if the author knows how to make it seem a good biography; or you can say the same thing backwards—That a good biography is as interesting as a good novel.

—EDWARD EVERETT HALE

In fact many of the old "Memoirs," purporting to be autobiographies were aptly characterised and described in the *Tatler* as novels.

THE PLATFORM

All that is necessary to raise a piece of imbecility into what the mob regards as a piece of profundity is to lift it off the floor and put it on a platform. Half the things that are said from a pulpit or rostrum or stage would get their spokesmen the bum's rush if they enunciated them five feet nearer the sea level.

—H. L. MENCKEN

CORRESPONDENCE

PSYCHIATROGENIC ILLNESS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Dr. Chapman, in his important paper, "Psychiatrogenic Illness," draws timely attention to the dangers of an indiscriminate and unthinking psychiatric therapy.

Many experienced practitioners have reported dire results (psychosis, delinquency or deterioration) of psychoanalysis applied to unsuited cases or in an unskilled manner. Freud himself recommended a three-week trial analysis before actually accepting them for treatment. As I tried to show (Psychiat. Quart., April 1958), it has not as yet been substantiated that insight therapy gets necessarily better results than other forms of treatment, or even of leaving the patient untreated.

Since results of psychotherapy have not as yet been scrutinized as they would in other medical specialties, we should carefully weigh the sacrifices in time and money, the possible family, social and other disadvantages, before embarking on any prolonged course of treatment. It is not just a question of deciding on treatment or not, but on being able to modify the treatment according to the needs of the patient, to have sufficient clinical judgment to observe incipient deteriorations, and know how to counter them.

Planned, elastic, patient centred, situation conscious, family and community oriented therapy, rather than method dominated, one track mentality, is needed.

Melitta Schmideberg, M.D.,
New York, N. Y.

ORDINAL POSITION IN THE FAMILY

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : I would like to comment on the significance of ordinal position in the family which has been touched upon in the paper by Ziegler, *et al.* in your April issue.

There have been no consistent findings in the literature on this aspect of personality development since Goodenough and Leahy (Pedagog. Sem. 34 : 45, 1927) published one of the earliest surveys in this field. The oldest, the middle and the youngest sibling has each, in turn, received special emphasis. Commenting on this, Harold Jones (in Murchinson C. : Handbook of Child Psychology, Clark University Press, 1933) cautioned that disagreement among psychoanalysts concerning birth order characteristics is in no sense greater than the disparities in statistical studies. He pointed out that a child's reaction to his own family setting may vary in an extremely complex manner and went so far as to urge that

any attempt to propose an emotional or motivational significance for birth rank itself may serve merely to obscure the observation of diverse and sometimes opposing factors.

More recently Helen Koch (J. Genet. Psychol. 88 : 231, 1956 ; Psychol. Monogr. 70, 1956) concluded from a most careful series of investigations that there is no ground for any sweeping generalizations about the effects of birth order on child characteristics and attitudes. We have investigated this problem in a group of adult schizophrenics (Science, 128 : 30, 1958) using a more controlled statistical design and have also in this disease found no ordinal position which would carry specific vulnerability.

Hanus J. Grosz, M.D.,
Postdoctoral Fellow,
Department of Medicine (Neurology)
Albert Einstein College of Medicine,
New York, N. Y.

CRITERIA FOR RESEARCH

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : You know, of course, that an awareness of research principles and methods is necessary in order to ascribe appropriate meaning to the wealth of psychological literature being published today. Therefore, the following findings and observations may be of interest to you and others.

This report comments on a systematic and rather thorough evaluation of the research methodology employed in the non-theoretical papers presented in the 6 leading psychiatric or psychological journals of 1958 as observed by Drs. Caruso, Subias, Vecozols, Vermeulen and myself during the series of informal seminars at the Columbia Psychiatric Institute and Hospital.

In this study the total field was pursued with extensive discussion on selected individual papers. This seminar, under the leadership of Dr. Benjamin Pasamanick, was the last of a series of three. The preceding two were concerned with the more basic fundamentals of research methodology and statistics.

We chose to make a total count of the research and theoretical papers. Of the former, we noted those with and without control. Those with controls were adjudged adequate or inadequate; the adequately controlled studies were observed in respect to the statistics used and whether or not the conclusions were justified.

Individual members of the group reported two papers, which were examined extensively, as a guide for the total evaluation. The criteria used were as follows :

1. The *hypothesis* : Was it formulated prior to the research ? Was it related to or derived from a body of theory ? Were the factors required for acceptance or rejection clearly stipulated ? Did it seem conceptually clear ? Was it testable ?

2. *Assumptions* implicit or explicit were sought, particularly the subtly included ones.

3. The *form* of the research must be explicit such as the internal factors of technique, sampling, design, controls, and analysis, as well as the external factors of size, objectivity, and reliability.

4. The *conclusions* were questioned in terms of the degree to which they were justified.

5. *Generalizations and interpretations* were scrutinized for validity.

Of almost 500 papers examined, nearly two-thirds were superficially categorized as research investigation ; yet, about one-third of these were completely without controls. Of those purporting to be controlled, approximately 75% were actually adjudged to employ adequate or appropriate controls. The group of suitably-controlled studies was felt to have valid conclusions in 75% of the cases and the presence of seemingly good and reliable statistics in upwards of 90% of the studies. Is it possible then that the final result shows that good and adequate research is present in only one-third of the research papers ?

The implications are fairly obvious and immediately somewhat disillusioning. In other words, perhaps not all those who say, "Lo, Lo, this is research ; come and see it !," are actually entitled response to their pompous command. One may quite rightly be dismayed at the common practice of reading only the conclusions and/or summary ; and yet, this represents one cause for the wide dissemination of truly unscientific material.

The results of our study immediately impress one with the need for journal editors to check an ever-increasing backlog of investigation flooding our academic attention. These investigations we are forced to view with increasing skepticism and uncertainty which require us to wait until the slow moving test of time establishes it, or the wheels of progress bring it into obscurity by sheer necessity of an individual's inability to encompass so much, whether of merit or not.

Conclusions though warranted should not, then, become too widely generalized, but open to replication in the process of its acceptance and application in other areas. We recognize that theoretical observations admittedly are important and need not feel challenged by this emphasis on research.

First of all, research methodology should

be an integral part of medical school education and certainly a part of the residency program. Only with this training can the reader intelligently be aware of the research processes and techniques involved as a basis for his individual acceptance or rejection.

Secondly, the editors of these journals must be reminded of their responsibility for a high degree of selectivity relative to papers sent in for publication, exercising

caution toward those papers in which the hypothesis is not clearly tested by adequately controlled uses of the scientific method, even though the mechanics of the research are sound.

These are my observations. Are there other ways this problem can be faced effectively?

Walter D. Hofmann, M.D.,
Division of Correction,
Columbus, Ohio.

AUTHORITY

The need for authority is a constant need of man. For it is the need for principles that are both stable enough and flexible enough to give direction to the processes of living in its vicissitudes and uncertainties . . . The underlying problem of recent centuries is the question of whether and how scientific method, which is the method of intelligence in experimental action, can provide the authority that earlier centuries sought in fixed dogmas. The conflict of science and religion is one phase of this conflict.

—JOHN DEWEY

THERE BUT BY THE GRACE OF GOD

One has only to grow older to become more tolerant. I see no fault that I might not have committed myself.

—GOETHE

SELF

In our present form of human consciousness the true self of any individual man is not a datum, but an ideal.

—JOSIAH ROYCE

NEWS AND NOTES

A GUIDE TO COMMUNITIES IN THE ESTABLISHMENT AND OPERATION OF PSYCHIATRIC CLINICS.—Of interest to individuals in the clinical professions and community groups is this new 309-page volume issued by the New York State Department of Mental Hygiene. The book answers numerous practical questions which confront those interested in setting up community psychiatric clinics. Attention is given to choice of auspices, cost, equipment, personnel, policy, and administration. Appendix material includes illustrative forms and guides, budgets, fee scales, as well as copies of the laws, regulations, and official documents pertaining to clinics.

The authors are Luther E. Woodward, Ph.D., and Winifred W. Arrington, M.S.S. Jesse E. Crampton contributed illustrative materials.

The book may be ordered through the Division of Community Services, New York State Department of Mental Hygiene, 240 State Street, Albany, N. Y., at \$2.00 per copy.

THE AMERICAN NEUROLOGICAL ASSOCIATION.—At the 85th annual meeting of the Association held in Boston, Mass., June 13-15, 1960, the following officers were elected for the year 1960-61: President, Harold G. Wolff; President-Elect, James L. O'Leary; 1st Vice-President, Harry M. Zimmerman; 2nd Vice-President, Raymond D. Adams; Secretary-Treasurer, Melvin D. Yahr; Assistant Secretary, Clark Millikan; Editor of Transactions, Melvin D. Yahr.

Dr. Derek Denny-Brown was elected to the council for 5 years and Dr. George A. Schumacher for 2 years. Dr. Augustus Rose was appointed representative to the American Board of Psychiatry and Neurology for 4 years, and Dr. J. Lawrence Pool was appointed as representative to the American Board of Neurological Surgery for 6 years.

Newly elected members 1960:

Active: Richard G. Berry, Christian Herrmann, Jr., Charles M. Luttrell, Clark T. Randt, Joseph G. Rushton, Robert D. Teasdale, John Nardini, Peritz Scheinberg, Alex-

ander Silverstein. Associate: Stanley M. Aronson, Juan M. Taveras, Hans-Lukas Teuber. Corresponding: Shibanosuke Katsuki. Honorary: Philip Bard, John F. Fulton, Sir Russell Brain.

Total registration was 629.

The 86th annual meeting will be held June 12-14, 1961, at the Claridge Hotel in Atlantic City, N. J.

DR. HENRY W. MILLER.—A Life Fellow of the American Psychiatric Association, Dr. Miller died at his home in Brewster, N. Y., June 22, 1960, aged 86. He was a graduate of the University of Toronto (1895) and spent most of his professional life in the United States. At one time he was clinical director of Saint Elizabeth's Hospital, Washington, D. C., afterward Superintendent of Maine State Hospital at Augusta. From 1914 to 1946 he was owner-superintendent of Mountainside Farm, a private mental institution at Brewster, N. Y.

From 1929 to 1949 Dr. Miller was associated with the College of P. & S., Columbia University, and in 1935 became associate attending Neurologist at Vanderbilt Clinic.

He had earlier served on the staffs of several mental hospitals in Massachusetts and Illinois.

ACADEMY OF PSYCHOANALYSIS.—Frances S. Arkin, M.D., one of the founders of the first psychoanalytic institute in this country connected with a medical school, was elected President of The Academy of Psychoanalysis for 1960-61. Other officers are: President-Elect, Roy R. Grinker, M.D.; Secretary, Joseph H. Merin, M.D.; Treasurer, John L. Schimel, M.D., and the following Trustees who will serve three year terms: Donald D. Jackson, M.D., May E. Romm, M.D., and Leon Salzman, M.D. The other officers of The Academy are: Past-President, John A. P. Millet, M.D.; Trustees: Nathan W. Ackerman, M.D., Ralph M. Crowley, M.D., Alexander Reid Martin, M.D., Leon J. Saul, M.D., and Natalie Shainess, M.D.

The mid-winter meeting of The Academy of Psychoanalysis will be held on Dec. 10 and 11, 1960, at the Hotel Biltmore in New York City. A symposium on values will be held on Dec. 10. 1. "Values, Truth and Psychoanalysis," by John R. Reid, M.D. 2. "Values, Maturation and Health," by A. H. Maslow, Ph.D. 3. Value Differences Between Patient and Psychoanalyst," by Janet Mackenzie Rioch, M.D. 4. "Values, Identity and Psychoanalysis," by Marianne H. Eckardt, M.D.

Inquiries may be addressed to Joseph H. Merin, M.D., Secretary, The Academy of Psychoanalysis, 125 East 65th Street, New York 21, N. Y.

NATIONAL BOARD OF MEDICAL EXAMINERS SETS UP SEPARATE EXAMINATION IN PSYCHIATRY.—On recommendation of a special *ad hoc* committee, chaired by Dr. Herbert Gaskill, professor of psychiatry, University of Colorado School of Medicine, the National Board of Examiners has decided to hold a separate examination in psychiatry, beginning with the Part II examination in April 1961. This places psychiatry on a par with medicine, surgery, pediatrics, obstetrics, gynecology, preventive medicine and public health in this examination. Previously, psychiatry was covered by relatively few questions in the medical test.

In his presidential address, Dr. Malamud referred to this move as "a very important development in the process of integrating psychiatry within medical education, with a beneficial impact on both."

EASTERN PSYCHIATRIC RESEARCH ASSOCIATION.—The following officers were elected at the June meeting of the Association. They will take office during the Annual meeting to be held at the Waldorf-Astoria Hotel, November 4-5, 1960.

President, Charles Buckman, M.D.; President-Elect, William Malamud, M.D.; 1st Vice-President, Emerick Friedman, M.D.; 2nd Vice-President, William Furst, M.D.; Secretary-Treasurer, David J. Impastato, M.D.; Asst. Secretary-Treasurer, Albert Browne-Mayers, M.D.; Councillors, William B. Terhune, M.D., Wilfred Dorfman, M.D., Robert E. Arnot, M.D.

N. Y. STATE PSYCHIATRIC SERVICES 1955-1960.—Commissioner Hoch, reporting to Governor Rockefeller makes a striking comparison of state hospital statistics of 1960 with those of 1955. Up to the latter year there had been a constant annual increase in resident population, averaging in recent years 2,000 patients. Had this annual increase continued, it is estimated that the 1960 hospital population would have exceeded that of 1955 by 10,000 patients. Instead there was a decrease of some 5,000 patients.

In striking contrast with these notable figures, there were 5,000 more patients admitted in 1960 than in 1955.

During the 5-year period the average hospital residence fell from 8 months to 6 months, and the discharge rate increased by 40%.

DISTRICT BRANCHES PUBLICATION 1.—Edited by Jacques S. Gottlieb, M.D., and Garfield Tournay, M.D., the 328-page volume contains the scientific papers and discussions which were presented at the Divisional Meeting, Midwest Area Branches of the APA, in Detroit, October 29-31, 1959. It is the first of a proposed series of publications that will report the proceedings of Divisional Meetings.

At the Detroit meeting the Academic Address, "New Horizons in Psychiatry" was given by William Malamud, M.D., President of the APA.

The Hon. G. Mennen Williams, Governor of the State of Michigan, gave an address titled "The Role of Government in Mental Health."

Orders should be addressed to: District Branches Publications, American Psychiatric Association, 1700 Eighteenth Street, N. W., Washington 9, D. C. Copies are \$3.00 each.

AMERICAN ASSOCIATION OF NEUROPATHOLOGISTS.—At the 36th annual meeting of the American Association of Neuropathologists, the following members were elected to serve as officers for the current year: President, Richard Richter, M.D., Chicago, Ill.; President-Elect, David Cowen, M.D., New York, N. Y.; Vice-President, Karl Neuberger, M.D., Denver, Col.; Secretary-

Treasurer, Leon Roizin, M.D., New York, N. Y.; Ass't Secretary-Treasurer, Irwin Feigin, M.D., New York, N. Y.

MEDICAL WRITERS' MEETING.—The 17th annual meeting of the American Medical Writers' Association will be held at the Hotel Morrison, Chicago, Sept. 30-Oct. 1, 1960. Dr. Austin Smith, President, Pharmaceutical Manufacturers Ass'n and former Editor, J.A.M.A., will preside.

The program Oct. 1 will be a "Conference on Medical Communications." Dr. Walter Kahoe, Director, Medical Dept., J. B. Lippincott Co., will preside at the morning session, which will be devoted to the publishing and editing aspects of medical writing. Dr. Justus J. Schifferes, Director, Health Education Council, will preside at the afternoon session, which will be devoted to the technique of medical writing.

At the banquet Sept. 30 several awards will be granted, including those in medical journalism, and to medical periodicals for distinguished service in journalism.

NEW CIVIL DEFENSE NATIONAL HEALTH PLAN.—A National Health Plan, issued by the Government and designed as an annex to the broader National Plan for Civil Defense and Defense Mobilization outlines the areas of responsibility, organization, functions and programs for health services under national emergency conditions including a survival and recovery period from a direct attack. Its major premise is the responsibility of individuals and of professional associations in health fields to take an active part in civil defense and defense mobilization and training in their communities. Assuming the disruption of health services and severe shortages of medical supplies and facilities, the Health Annex outlines ways of dealing with these problems. Of primary importance is the necessity for community members to be self-sufficient for a short time after an attack until help reaches them and the Plan suggests such preparedness measures as training in first aid and various

ways of meeting shortages. Under the Plan, while responsibility for health resources acquisition, management and control rests with the Office of Civil and Defense Mobilization, the primary responsibility in the Federal government for civil defense health and mobilization programs is assigned to the Department of Health, Education and Welfare.

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following candidates were certified as Diplomates in Child Psychiatry by this Board and its Committee on Certification in Child Psychiatry, April 1960.

James Milton Bell, CANAAN, N. Y.
Norman Ralph Bernstein, Boston, MASS.
A. Ferdinand Bonan, Philadelphia, Pa.
John Armistead Boston, Jr., Austin, TEX.
Jack Emile Chappuis, New Orleans, LA.
Walter F. Char, Philadelphia, Pa.
Richard Lawrence Cohen, West Chester, Pa.
Theodore Benjamin Cohen, Philadelphia, Pa.
Albert Victor Cuner, Buffalo, N. Y.
Carlo P. DeAnronio, Sherman Oaks, Calif.
Chester R. Dietz, Wilmington, Del.
Leon Eisenberg, Baltimore, Md.
Aaron H. Esman, New York, N. Y.
Stuart McIntyre Finch, Ann Arbor, Mich.
Joseph Fischhoff, Detroit, Mich.
Barbara Fish, New York, N. Y.
Robert B. Forman, Topeka, Kan.
Harry George Gianakon, Philadelphia, Pa.
Alfred J. Gianascol, San Francisco, Calif.
Arthur E. Gillman, New York, N. Y.
Joseph Martin Green, Madison, Wisc.
Robert L. Greenlee, Fort Wayne, Ind.
Harold Joseph Harris, Chapel Hill, N. C.
Melvin S. Heller, Philadelphia, Pa.
Richmond Holder, Boston, Mass.
Leonard Hollander, Bronx, N. Y.
Albert S. Hopkins, Forest Hills, N. Y.
Doris M. Hunter, Pittsburgh, Pa.
Jean D. Jameson, New York, N. Y.
Jacob Philip Kahn, San Francisco, Calif.
Harris Elliott Karowe, Schenectady, N. Y.
Michael Theodore Khlenzos, San Francisco, Calif.
Elizabeth Kleinberger, New York, N. Y.
LeRoy F. Kurlander, San Diego, Calif.
James Joseph Lawton, Jr., Minneapolis, Minn.
Edward Mortimer Lirin, Rochester, Minn.
Irwin M. Marcus, New Orleans, La.
John Tarlton Morrow, Jr., Topeka, Kan.
Byron Leon Nestor, Berkeley, Calif.
Joseph D. Noshpitz, Bethesda, Md.
Morris Parmet, Flemington, N. J.
Robert C. Prall, Philadelphia, Pa.
Francis T. Rafferty, Salt Lake City, Utah
John Belvin Reinhart, Pittsburgh, Pa.
Bertram Aaron Ruttenberg, Villanova, Pa.
Calvin Frederick Seelage, Ardmore, Pa.
Marvin I. Shapiro, Pittsburgh, Pa.
Malcolm Richard Sills, Worcester, Mass.
Archie Aaron Silver, New York, N. Y.
James E. Simmons, Indianapolis, Ind.
Meyer Sonis, Philadelphia, Pa.
James Neil Sussex, Birmingham, Ala.
Charles R. Swift, Trenton, N. J.
David S. Thorsen, St. Paul, Minn.
Jack Vance Wallinga, Minneapolis, Minn.
Richard Storer Ward, New York, N. Y.
Morris Weiss, Detroit, Mich.
Virginia Nichols Wilking, New York, N. Y.
Henry H. Work, Los Angeles, Calif.
Stephen C. Wright, Miami, Fla.
Thomas S. Wright, Abington, Pa.
Howard Lee Wylie, Pittsburgh, Pa.

BOOK REVIEWS

SOCIAL SCIENCE AND SOCIAL PATHOLOGY. By Barbara Wootton. (London: George Allen & Unwin, 1959, pp. 400. \$7.75.)

Barbara Wootton is an exceptional figure on the British intellectual scene, combining as she does the critical abilities of an academic social scientist, the practical experience of a magistrate and the authority of a peeress of the realm. She enjoys a well-merited reputation for clear thinking and blunt speaking and her gifts of self expression are such as to have mollified the most critical reviewers. Ten years ago her *Testament for Social Science* set out the credo of a rationalist who maintained that the social sciences should and could be applied scientifically in the solution of many social and political problems. Since the publication of that book Lady Wootton has given intimations of an ominous disquiet as she has become more familiar with the field of social pathology. These occasional rumbles can now be seen to have presaged the thunderclap of her present volume in which it is apparent that she is profoundly disturbed by what she has come to know.

The scope of *Social Science and Social Pathology* is considerable, though the aim of the book is explicitly limited to "an assessment of the results of researches already undertaken by others" and its purpose is ostensibly no more than "to stop and ask ourselves where we are going and why." Part I purports to survey "the nature and extent of social pathology in contemporary Britain, reviews the findings of a number of studies, and attempts both to assess the findings relating to several of the currently most popular hypotheses and to estimate the success of some experiments in prediction." Part II, which will probably be of most immediate interest to readers of this journal, deals with "... change in contemporary attitudes towards unwelcome deviants, and in particular with the tremendous revolution both in the world at large and amongst professional social workers in particular, which is due to the rise of psychiatry." Part III is concerned with the conclusions "... relevant, not only to research in social pathology but to the social sciences in general." There is also an interesting and valuable appendix on professionalism in social work done by one of the two assistants who have helped compile the material on which the work is based.

At what conclusions does the author arrive?

To the chagrin of the enthusiast they are that "... the chief effect of precise investigations into questions of social pathology has been to undermine the credibility of virtually all the current myths," and that "such destructive activity is likely for some time to come to be the main preoccupation of the social sciences." The bulk of the volume is devoted to a detailed and mythoclastic survey of current viewpoints and the studies on which they are based. One after another the windy claims of the eugenicists, the woolly theories of criminal behaviour, the fashionable jeremiads on the theme of maternal separation and the ritualism of psychiatric social work are despatched with exhilarating efficiency in the best English empirical tradition. In full sail Lady Wootton is a splendid sight and the text abounds with memorable and incisive thrusts as her arguments gather force. Three examples must suffice: "the psychiatric approach to social work makes it possible simultaneously to disown and to retain the attitude of superior wisdom and insight traditionally adopted by the rich towards the poor"; "the lamentable arrogance of the language in which contemporary social workers describe their activities is not generally matched by the work they actually do: otherwise it is hardly credible that they would not constantly get their faces slapped"; "always it is easier to put up a clinic than to pull down a slum."

It is probable that few workers in the professional groups which have been organised to tackle socio-medical problems will be able to avoid a re-examination of the foundations of their beliefs and activities after reading this book. It is also probable that some of them will be upset by it. Lady Wootton has delivered douches of cold water to a number of over-heated topics and this procedure can be uncomfortable even if its medicinal value be indisputable. When she provides a modicum of consolation it sparkles in the ashes, but many psychiatrists, for example, will feel inadequately rewarded to learn that "whatever may be thought of the scientific pretensions of psychiatry, there can be no question as to its humanising effect upon the treatment of socially refractory persons." Perhaps Lady Wootton's most valuable positive contribution is her searching discussion of the need for the rescue of moral values from contemporary enemies, for "medical science," as she says, "walks in at the door as moral judgment flies out of the

window." The issues of criminal responsibility open the way to a full examination of this thesis and we are forcibly reminded of the fact that "in psychiatrically orientated social work . . . just as in psychotherapy itself, moral judgments may lie concealed in what appears to be the neutral language of science or medicine."

There are, to be sure, a number of points at which to cavil. Many critics would dispute the author's view that ". . . it is in their role as the handmaidens of practical decision that the social sciences can shine most brightly." Others might object that her arguments against drawing a distinction between causation and prediction are suspect or that her faith in prediction tables is premature. Lady Wootton does little to indicate that the flaws in many of the studies which she castigates are clearly recognised by a growing number of workers in the field of social psychiatry, especially those who are familiar with the basis of epidemiological theory. She is also not above quoting out of context on occasion. Nonetheless, such defects do not detract substantially from the overall value of a book which will so certainly stimulate its readers, some to admiration, others to anger. Lady Wootton has performed a valuable service for which we must all be grateful. We shall be in her debt still further if she will now go on to develop suggestions for reconstruction after the storm.

MICHAEL SHEPHERD, D.M.,
The Maudsley Hospital,
London, England.

THE SYMPTOM AS COMMUNICATION IN SCHIZOPHRENIA. Edited by Lieutenant Colonel Kenneth L. Artiss MC. (New York: Grune and Stratton, 1959, pp. 233. \$5.75.)

DIE BEGINNENDE SCHIZOPHRENIE. By K. Conrad. (Stuttgart: Georg Thieme, 1958, pp. 165. \$4.10.)

In recent years the problem of communication with schizophrenics has attracted a considerable amount of attention. The reports presented in the book entitled *The Symptom as Communication in Schizophrenia* represent clinical research in the problem of schizophrenia undertaken in a military setting where there are aspects unique to that setting.

Following an introduction by Dr. David McK. Rioch, Director of the Division of Neuropsychiatry, Walter Reed Army Institute of Research, there are 7 sections by 5 contributors (K. L. Artiss, B. L. Bushard, D. H. Marlowe, K. T. Erickson, and R. H. Rowe).

The section discussing "the symptom as an informative and communicative device" sets forth the concept of the symptom as a message with an anticipated reply. The "group" is defined and interaction explored. In an interdisciplinary study, psychiatry, social work, sociology and anthropology have been brought together, the object being to clarify observations concerning behavior.

The section entitled "the symptom in a formal organization" deals with the problem of the management of schizophrenia in the U. S. Army. The Army treatment of neurosis has been relatively successful in contrast to the results with schizophrenia. Schizophrenia is the predominant psychosis in the Army. It constitutes a high percentage of psychotic disorders. Moreover, "of all disability discharges for non-battle injuries and disease, 24.7% are based on schizophrenia." The research here "strives for a fuller understanding of the facts in the life history of soldiers who develop schizophrenic symptoms" and to "trace the development of such symptoms from their earliest appearance, through the various forms in which they manifest themselves," and the various circumstances that brought the patient to medical attention. One principal objective is to develop new techniques for rehabilitation.

The third section presents the "Methodology of the Study," describing home and community studies, tape recorded squad interviews, Fiedler Assumed Similarity Studies, sociometrics, and ward observation procedures. There are 5 general areas of investigation as outlined by the author (Bushard). 1. The background investigation: a study of family, school, community and work adjustment. 2. The military adjustment prior to hospitalization. 3. The examination prior to and immediately following initial hospitalization. 4. Observations during further hospitalization and treatment. 5. Follow-up of adjustment following release from the hospital.

In sections 4 and 5 the problems arising in the basic training are discussed. The anxiety produced during the first 4 weeks of training is explored and the group methods of dealing with it are described. The schizophrenic reactions in basic training are of particular importance for study, as the findings have revealed dominant behavior patterns. Schizophrenics are detected early by their associates because of poor performance, and odd behavior.

In the sixth section the significance of the symptom in the past history of the patient is discussed. Field studies in the home and community are reported, as approached by a num-

ber of new successful techniques which provide evidence from school and community adjustment indicating a long history characterizing schizophrenic disorders. The seventh and last part emphasizes the value of the symptom during treatment. Here are given an account of the detailed studies with results obtained from "milieu therapy" ward.

As a whole, this book presents an interesting and informative account of search and research objectives and results important to psychiatric workers everywhere.

The monograph in German entitled *Die Beginnende Schizophrenie* by Prof. Dr. K. Conrad, Director of the Neurological Clinic of the University of Göttingen, presents a study of the subject from the viewpoint of gestalt analysis. Following a discussion of the present situation with regard to the knowledge of the schizophrenic disorder, the author presents, in some detail, an example case of Shube's schizophrenia, including the therapy and work plan.

The gestalt analysis and interpretation of schizophrenic manifestations includes the withdrawal from reality phenomena, the fantasies, the initial depression, the projection mechanisms and misinterpretations, disorders of perception of space and time, the feelings of estrangement and those of omnipotence are brought into the total gestalt picture. During this phase there is also considered the thought spreading, hallucinated voices, odd bodily sensations and the general structure of schizophrenic thought.

The catatonic psychosis phase with its special features, the consolidation and end states achieved are well described. The main text is concluded with a description of the courses of the clinical types (The "Shube" and the "process"). An appendix presents a brief description of non-schizophrenic delusion formations and also a discussion of the case of Rene (Schehaye). The text is liberally illustrated by case notes referring to symptoms and management. Students of gestalt psychology will be interested in these applications of the theory.

New York, N. Y.

A HISTORY OF NEUROLOGY. By Walter Riese.
(New York: MD Publications Inc., 1958,
pp. 223. \$4.00)

The book under review is largely a discursive philosophical treatise. The author discusses general neurological ideas and pays comparatively little heed to structure and func-

tion, the scientific bases of neurology. The 9 chapters in the book deal successively with the history of concepts: The Nervous Impulse, Reflex Action, The Doctrine of Cerebral Localization, Rediscovery of the Whole, Ancient and Modern Pain in Neurology, and The Histories of Diagnosis, Prognosis and Therapy in Neurology. Of the last 3, Diagnosis receives 10 pages, Prognosis 2 and Therapy 7. It is not clear what the chapter on The Rediscovery of the "Whole" seeks to convey and what link there is between Galen's speculations and Monakow's theory of diaschisis. Nor is it clear what is meant by the Doctrine of Cerebral Localization when so little is said on neuroanatomy, neurophysiology and clinical medicine.

It is a common failing of enthusiastic historians to attribute to ancient authors knowledge of which they were innocent and to credit them with scientific insight of which they were obviously bereft. Clearly, hunches and guesses, however interesting, are not scientifically proved facts. It is true, for instance, that Erasistratus (4th century B.C.) alluded vaguely to "nerves" of motion and sensation, but like others he believed the nerves were tubes, which were confused with tendons, and it was not till 22 centuries later that Bell and Megendie provided scientific proof. Much too much credit is given to Galen and Rufus of Ephesus and Plato and Aristotle, who, like many philosophers throughout the ages, retarded knowledge with metaphysical speculation.

Although the author occasionally puts a quotation mark on the word "soul," the repeated introduction of a religious concept in the scientific study of neurology arouses wonder and doubt. Despite the lengthy bibliography of 175 references, 22 of them to the author, a host of important ones are left out. Most of the anatomists, neurosurgeons and clinicians who created the modern scientific specialty are not mentioned, at most barely alluded to. We are told that it is one generation since Westphal. Actually it is three generations. He became the first professor of neurology in a German university in 1870.

It is a strange fact that of all medical specialties neurology alone has failed to receive the attention of medical historians which it so richly deserves. Ancient authors have received attention, so have a number of neurologists of fame, and there are a few monographs sketching short periods, but there are no full length histories, aside from the reviewer's "Brief History of Neurology," included in his Textbook. This reviewer anticipated hopefully that the

present volume of the scholarly author would fill the need. Regretfully, the history of philosophical concepts is not a history of neurology.

New York, N. Y.

CAN MAN BE MODIFIED? By Jean Rostand.
(New York: Basic Books, Inc., 1959,
pp. 105. \$3.00.)

There is magic in the name Rostand. Did not Rostand, *père*, till then a youthful poet of no great celebrity, create the immortal *Cyrano de Bergerac*? And dedicate it in such exquisite phrase to the man for whom it was written, the great French actor Coquelin:

*C'est à l'âme de Cyrano que je voulais
dédier ce poème*

*Mais puisqu'elle a passé en vous, CO-
QUELIN, c'est à vous que je le dédie*

And now Rostand, *fil*, in this small volume carries the magic into the field of experimental biology, much of it his own work. Reminding us that fatherless sea-urchins were developed chemically in the laboratory half a century ago, he tells us that in the recent past the permanent secretary of the Académie des Sciences "referred quite calmly to the prospect of solitary generation for human beings." By suitably doubling the chromosomes in the eggs of frogs, not only parthenogenesis but androgenesis is possible. Through the process of tissue culture experiments in physical immortality are going on, and "human propagation by cuttings" should make it possible "to create as many identical individuals as might be desired . . . all of them real twins."

What a boon to war makers!

The miracles of contemporary experimental biology are many and the author gives a number of the startling if not frightening examples of the transformations man can bring about in various forms of life, even the human species. Speaking of both animals and plants, he says: "We can produce *artificial mutations* and cause new races of living creatures to appear on earth." But in spite of all these marvels the fundamental problem of life itself has not been solved,—not yet. And we must not be too forward with our prophecies, hopes or fears. Here Rostand appositely quotes the great Claude Bernard, speaking of living organisms: "We must not read into them either a chemical retort or a soul: *we must read into them what is there.*"

But the future possibilities of biology seem almost limitless. "Biology can, in fact, set to work to modify the organ of thought itself—the living brain" and thus conceivably produce

supermen. Accordingly "it is plain that, from progress to progress, from one advance to another, science may go on expanding indefinitely."

The author pays his respects to Aldous Huxley's *Brave New World* (1931). Ectogenesis, he says, is not altogether a mad dream. "This vision of the future is based on a precise knowledge of the present." Eugenic selection also comes under consideration. "Until human selection has been tried, nobody has the right to assign an upper limit to man." It was Goethe, Rostand reminds us, who in *Faust* first used the word *Übermensch* (incidentally it was the devil who spoke it—and in derision) that Nietzsche made so much of.

Having outlined the miracles of science as applied to biology and specified the possibilities of the future—even the probabilities, Rostand in his concluding pages comes upon stumbling blocks. He asks the question: "Is the creation of such a superman desirable?" And he seems somewhat uncertain about answering in the affirmative. Taking note of the slow evolutionary process in nature which has left the contemporary human mind not essentially better than that of early mankind, he hesitates before "the idea of an evolution controlled and directed by man," although the science to which he has given his own life appears to lead that way. He gives audience to echoes from an anthropocentric medieval world. "Man," he says, "cannot help regarding himself as something sacred . . . as the highest and most precious thing on the planet . . . as that 'unique being' . . . which perhaps has not its like in the whole of the vast universe." This sounds perilously like the standpoint of the old ecclesiastical man who was the very center of the universe, around whom the sun and planets and the fixed stars revolved for his special welfare and delectation.

The reviewer found M. Rostand somewhat difficult to follow through these last pages. He seemed to consider seriously the artificial dichotomy between science and not-science and to pause before a sort of walled off transcendental world the scientist with his crude tools may not enter. He then considers a possible bridge between the two worlds, or as he puts it "between science and conscience," namely the science of mind, particularly as represented by psychoanalysis. By this means he suggests an all-embracing love might be introduced into the world and lead to "a lofty 'scientific morality'" ('love' remains undefined). But leaving romance aside for a moment, one seems to remember that Dewey commented critically on the unfortunate ob-

stacle to free enquiry of halting before a restricted area of human experience beyond the reach of science. After all a transcendental world, whatever else it is, can only be known as a part of human experience just as the weather is and should be examined with a free mind by applying the same principles of scientific enquiry.

Despite what may seem like an anticlimax in the final section of this remarkable book, we may be sure that Rostand, the magician, will pursue his researches along his destined way leading to new miracles in the life of animals, not excluding the paragon of animals, in a braver new world, perhaps.

C. B. F.

THE MOTHERS OF SCHIZOPHRENIC PATIENTS.

By Yrjö Alanen. (Copenhagen: Ejnar Munksgaard, 1958, pp. 361.)

This is a most remarkable monograph reporting a study of 100 unselected schizophrenic patients and their mothers as well as 20 neurotic and 20 "normal" persons and their mothers. The author aims to clarify 3 questions: 1. What descriptive and psychodynamic traits can be discerned in the mothers of schizophrenic patients by means of interviews and the Rorschach tests? 2. What characteristics do the relationships of mothers to their children developing schizophrenia display in contrast with control cases? and 3. What conclusions can possibly be drawn as to the pathogenic role of the mother-child relationship in the development of schizophrenia? The author then proceeds to give in less than 100 pages a summary and critical review of schizophrenia research and of theories and studies aimed at clarification of etiology. This section alone is a remarkable achievement, a model of a concise, critical review of scientific and clinical material.

The schizophrenic study material is subdivided into 2 groups according to the European concept *i.e.*, patients with "process schizophrenia" (severe or unquestionable cases in American parlance) are treated as a separate group from those diagnosed as psychosis schizophreniformis (acute schizophrenic reaction, pseudoneurotic schizophrenia, *etc.* in American writings) and the material is further subdivided according to age of onset, and a small group of 5 schizophrenic patients is treated separately because of a pre-existing chronic organic illness. It may be giving the plot away by stating that the overall findings and conclusions of the author were not affected by this careful grouping of the patient

material. The author has given consideration in a separate chapter to the possible interpretation and formulation of his material from a viewpoint of heredity and genetics. But without attempting to arbitrate the case for or against hereditary influences in the development of schizophrenia, he emphasizes the "non-hereditary transmission of psychosis" brought about by the behavior and rearing techniques of a disturbed parent and the ensuing disturbed interaction between parent and the future patient. Although the study is limited to that of patient and mother, he does emphasize that in those 16 instances where the mother's personality was considered more or less normal there was a severely disturbed father who influenced the family environment adversely, at least for the patient-offspring. There are also a few data concerning the mother's particular problems during pregnancy with the patient and her attitudes towards him during early childhood, as compared with the mother's situation when non-schizophrenic siblings were born. Although this material is sparse, the author has shown how factors and data to explain the differential development of schizophrenic and non-schizophrenic children in the same family might be obtained and obtainable. Other data such as the incidence of psychosomatic illness in these 100 mothers, or the detailed configuration of the mother's personalities are of interest regardless of their significance to the main theme.

The techniques employed are those of interviewing and projective tests done independently, and the author carefully asserts the methodological limitations. In his conclusions he emphasizes which theories are not borne out by his findings rather than advancing new etiological hypotheses based on his findings. This monograph is essential to all students of schizophrenia.

STEPHEN FLECK, M.D.,

Yale University School of Medicine,
New Haven, Conn.

THE FIFTH MENTAL MEASUREMENTS YEAR-BOOK. Edited by Oscar K. Buros. (Highland Park, N. J.: The Gryphon Press, 1959, pp. 1292. \$22.50.)

The value of Buros' 8 volumes of tests and test books reviews has increased since his first annotated bibliography appeared in 1933, to the stage where now "The Buros" is the major, if not the only, comprehensive source of information for persons who use tests and test results. The present volume covers tests and tests books published since 1952, as well as

new critiques of tests previously reviewed. For a comprehensive coverage of tests and books on testing now being sold, the 1953, 1947 and 1941 publications are required as well. It is scarcely necessary to refer to the careful work that characterizes this series. Buros has uncovered more than 2200 Rorschach technique studies and articles alone! A glance at the list of reviewers will assure the reader that this job has been delegated to eminent specialists in each field, while the reviews themselves show that they have not taken their responsibilities lightly. The reader is advised to study the Preface carefully in order to familiarize himself with the organiza-

tion of the book before attempting to locate a reference, for, while the organization is simple, it is not immediately evident from the index listings. Books, for instance, are now reviewed in a section separate from the actual tests. With the continuing development, stricter control of design and distribution, and increasingly confusing number of tests available, the Buros yearbooks become reference requisites for clinics, institutions and research centers where psychological tests form part of the assessment program.

Toronto, Ont.

NEW GERMAN PSYCHIATRICA AND PSYCHOLOGICA

HANS A. ILLING, Ph.D., Lds ANGELES, CAL.

DIE BEGINNENDE SCHIZOPHRENIE. By K. Conrad, M.D. (Stuttgart: Georg Thieme Verlag, 1959, pp. 165, DM 17.80—or Intercontinental Medical Book Corporation, New York. \$4.50.)

The present study aims to "continue a great past," the teaching of psychopathology by Jaspers and the "Heidelberg-School" (Wilmanns, Grubbe, K. Schneider, Mayer-Gross, Buerger-Prinz, et al.). The author feels that the Heidelberg School had come to a "dead-end," since it aimed to dissect the psyche into its basic elements and functions. The author coins two new phrases relating to schizophrenia: *apophaenie*, meaning the experience of the abnormal consciousness as it relates to values, and the *anastrophe*, the experience of the schizophrenic who feels that everything is centered around him. The author does not offer any "cure," but admits that certain "residues" remain.

DIE GRUNDLAGEN DER REHABILITATION IN DER BUNDESREPUBLIK DEUTSCHLAND. By Kurt-Alphons Jochheim, M.D. (Stuttgart: Georg Thieme Verlag, 1959, pp. 203, DM 24.00—or Intercontinental Medical Book Corporation, New York. \$5.70.)

This volume, one in a series of socio-medical monographs, describes first the development and trends of rehabilitative programs in America, England, France, Sweden, Holland, Austria, and Switzerland. After a few brief chapters on medical insurance, social security, and vocational counseling, the author discusses infant, child, and adolescent illnesses (epilepsy, mental deficiency, spasticism, paraplegic and

congenital illnesses) and illnesses of the adult years (tbc, cardiac, arthritic, neurological etiologies, and poliomyelitis), and closes with a chapter on the various health agencies in West Germany dealing with any or all of the rehabilitative aspects of these illnesses.

DAS MENSCHENBILD DER SEELENHEILKUNDE. By Victor E. Frankl, M.D. (Stuttgart: Hippokrates Verlag, 1959, pp. 128, DM 8, 50.)

This monograph consists of 3 lectures, which the author delivered at the University of Salzburg (Austria) in 1957. The informal lectures deal with a multitude of topics, such as the pros and cons of psychoanalysis (Frankl feels, for instance, that Freud's concept is "one-sided and incomplete" and, therefore, is a "half-truth more dangerous than a full-blown error"), the pathology of *der Zeitgeist*, of which the author says that *die kollektive Neurose der Menschheit laesst sich nicht ueberwinden* (the mass neuroses of mankind cannot be resolved), and philosophical and anthropological subjects, often taken from American literature.

KOERPERLICHE UND GEISTIGE EIGNUNG ZUM FUEHREN VON KRAFTFAHRZEUGEN BEI HIRN-VERLETZTEN. (Physical and Mental Ability of the Brain-Injured in Driving Automobiles.) By Artur Grossjahn, M. D. (Stuttgart: Georg Thieme Verlag, 1958, pp. 84, DM 7, 50—or Intercontinental Medical Book Corporation, New York. \$1.80.)

The present monograph is the outgrowth of a study of hundreds of persons whose brain was injured in automobile accidents during the last 5 years up to the conclusion of the study

in 1956. Of the 18 "results" drawn from this study, it seems that more "slightly" than "seriously" brain-injured patients were found; that the injuries to the body as a whole were more important than those to the brain alone; and that, "unconditionally," one third of all the brain-injured became "fully capacitated" to drive automobiles.

PSYCHOTHERAPIE. By D. Mueller-Hegemann. (Berlin: VEB Verlag Volk und Gesundheit, 1959, pp. 264, DM 24.00.)

The aim of the author is to provide a *Leitfaden*—a guide—for medical students and beginning medical practitioners in "psychotherapy." However, the author's own definition of psychotherapy, as compared with most European and American conceptions of it, seems to be dated. Thus his historical narrative demonstrates: "modern" times in the history of psychotherapy start with Mesmer and "end" with Pavlov, with a mention of Flugel, the non-medical analyst in England. Freud and his followers and dissenters receive only "honorable" mention, except that Freud's teachings are said to have contributed to the "ever-increasing gap between depth-psychology and traditional clinical medicine." When the author, for instance, discusses group psychotherapy, he seems to assume that nothing has been done before him, unless it be a Pavlovian type of "therapy," which, according to him, is "work-therapy!"

EIN MODERNER MYTHOS. VON DINGEN DIE AM HIMMEL GEGEHEN WERDEN. By C. G. Jung. (Zurich, Switzerland: Rascher-Verlag, 1958, pp. 112, Sfrs. 8.40, and its translation: **FLYING SAUCERS. A MODERN MYTH OF THINGS SEEN IN THE SKIES.** New York: Harcourt, Brace, 1959, pp. 185. \$3.95.)

The English translation has 3 advantages over the Swiss edition: it is cloth bound and richly illustrated, and carries a Preface written by Prof. Jung himself for the English translation. In it, Jung asserts that the question whether the Flying Saucers are "real" or a "mere fantasy product" is by no means settled yet. The purpose of his book is to examine both sides of the story. What are the saucers, if they are real? If they are imagination, why should the rumors of their existence persist? Prof. Jung has done some research into the Ufos (unidentified flying objects), in the course of which he was "suspected" of being a "believer" in their reality. He feels, however, that

the whole matter of the Ufos deserves the "psychologist's interest." And the book attempts to answer the question why it should be more desirable for saucers to exist than not.

DAS MAERCHEN UND DIE PHANTASIE DES KINDES. By Charlotte Buhler, Ph.D., and Josephine Bilz, M.D. (Munich: Johann Ambrosius Barth, 1958, pp. 111, DM 12.50.)

Dr. Buhler, who is presently clinical professor of psychiatry at the University of Southern California, first published this monograph in 1918. The present edition, however, is not merely a reprint of a monograph long out of print, but a discussion by Josephine Bilz, who examines the experiences and events of the fairy-tale from the point of view of depth psychology. In the Introduction, written by Hildegard Hetzer, M.D., Charlotte Buhler's applications to child psychology are evaluated, and both "reality" and *Wunder*—miracles—in fairy-tales are examined. All 3 authors are scholarly, and the monograph appears to be of immense value to the child psychologist and child psychiatrist.

DIE PSYCHOTHERAPIE DER GEGENWART. Edited by Erich Stern, M.D. (Zurich: Rascher-Verlag, 1959, pp. 474, Sfrs. 33.00.)

This compendium contains two sections, one on the main trends of modern psychotherapy, and the other on their application, *Grenzgebiete* (associate fields) and problems, with a summary of both sections by the editor.

The compendium is international in scope and international in the selection of its contributors, each one of them an authority in his *Richtung*. Thus Rudolf Dreikurs (Chicago) discusses Adler's Individual Psychology, Berthold Stokvis (Holland) elaborates on hypnosis, suggestibility, and relaxation-therapy, L. Gayral (France) discourses on narcoanalysis, Alfred Storch (Switzerland) on Existentialism, S. R. Slavson (New York) on group psychotherapy, and A. R. Bodenheimer and Christian Mueller (both of Switzerland), each in one paper, on psychotherapy with psychotics intrapaper and extrapaper. There is Prof. Heinrich Meng's excellent expose of "Psychiatrie" in *menschenoeconomischer Hinsicht*—socio-economic aspects,—a topic which Meng has pioneered in Europe for many years. All told, this volume appears to be a beautiful accomplishment of cross-fertilization of both hemispheres and, therefore, of great value for the comparative study of psychotherapeutic methods.

PSYCHIATRIE UND GESELLSCHAFT. ERGEBNISSE UND PROBLEME DER SOZIALPSYCHIATRIE. Edited by H. Ehrhardt, D. Ploog, and H. Stutte. (Berne, Switzerland: Verlag Hans Huber, 1959, pp. 320, Sfrs. 31.50. In U. S.: Intercontinental Medical Book Corporation, New York. \$7.50.)

The concept of "social" psychiatry (which originated in England and was "imported" here) finally is "invading" Continental Europe. The present volume should serve the "Cosmopolitan" and sophisticated professional reader all the better because, in part, some of the articles are written in English and French. Thus Frederick Redlich of Yale University writes on "Social Class, Culture and Schizophrenia," Oscar Diethelm of Cornell University and the New York Hospital on "Social Psychiatry in North America," J. R. Rees and Kenneth Soddy on "Mental Health and Mental Hygiene as International Tasks," Leo Kanner of the Johns Hopkins Hospital on "Parental Perfectionism as a Pathogenic Agent," (in German translation), E. Strauss of the V.A. Hospital in Lexington, Ky., on *Formen und Formen*, and George S. Stevenson on "Psychological Hygiene in the U. S." Other authors are from Germany, Austria, Switzerland, Holland, and France. The articles are divided into five main topics: psychiatry and the milieu, psychopathology of various etiologies (sex and sociology, psychoses, the dynamics of "group psychiatry," modern arts, etc.), psychiatry and psychohygiene, child psychiatry, crime and delinquency, and institutional psychiatry.

PSYCHIATRY AND THE CRIMINAL. By John M. McDonald, M.D. (Springfield: Charles C Thomas, 1957, pp. 227. \$5.50.)

A practical, systematic, and reasonably comprehensive book on forensic psychiatry is at hand, in "Psychiatry and the Criminal." Here are all the detail, illustrating examples, and inside tips which only a professional thoroughly familiar with the field can provide. Where to write for armed forces records, blood alcohol levels, case history outlines, intelligence classifications, and other frequently used information, are included, along with discussions of their significance and application. But this volume is no handbook, for it includes chapters on the origins of criminal behavior, tests for criminal responsibility, psychiatric examinations, the Ganser syndrome, narcoanalysis, amnesia, epilepsy, psychopaths, sex offenders, juveniles, psychological tests, witness stand techniques,

and treatment and punishment. Written with erudition and diversity, this material is organized into what should serve as the best teaching text in this field. The aim of the book, of providing a practical guide to psychiatric examination of suspected criminals, is so admirably achieved that the unavoidable limitations on depth of discussion are hardly noticeable. But by perceptive quotations, the author reminds us that there is more, much more, to be said.

RICHARD G. BOARD, M.D.,
Washington, D. C.

RECREATION ACTIVITIES FOR THE HANDICAPPED. By Frederick M. Chapman. (New York: The Ronald Press, 1960, pp. 309. \$5.75.)

The author has appropriately termed his book "practical." Part I outlines the need of the handicapped, in common with all people, for satisfying recreation activities, both in the community and in hospitals. Recreation needs are grouped according to age-behavioural characteristics, and also in 6 diagnostic groups. The ingredients of leadership are described and multi-disciplinary sharing in this programme is noted.

Part II comprises working descriptions, instructions, etc., for a wide variety of activities, with the appropriate age and diagnostic groups indicated for each. Included are: some 38 activities related to crafts, audio-visual, drama, dancing, musical activities, special interests, social recreation, sports and games.

The fact that the approach and the material are not new to those familiar with occupational therapy literature makes it no less valuable, as it is well organized, practical material which is clearly described and cross indexed.

HELEN P. LEVESCONTE, O.T.REG.,
University of Toronto.

REMBRANDT'S ANATOMY OF DR. NICOLAAS TULP. By William S. Heckscher. (New York: New York University Press, 1958, pp. 217, 85 illus. \$15.00.)

Rembrandt's famous painting, often called "The Anatomy Lesson" is known to all the civilized world. It was executed when Rembrandt was only 26 years of age and had just settled in Amsterdam. The painting is now one of the chief ornaments of the Mauritshuis at the Hague. In the present volume, Professor Heckscher, who is Director of the Iconological Institute of the University of Utrecht, inquires into the origins of this painting done by Rembrandt in 1632. He is interested in the

cultural context which the painting reflects, and his task is one of historical reconstruction. Rembrandt, the great master of light and shadow, is fortunate in his interpreter, for with Professor Heckscher's analysis we now have for the first time, what is probably a sound account of the meaning of this not very enigmatic work. Enigmatic or not, Rembrandt's painting has long been misinterpreted as Professor Tulp giving a lesson to his ardent colleagues in anatomy. It has long been known that the men in the painting were not Tulp's anatomical colleagues, but it was thought that what was being portrayed was a lesson in anatomy. Apparently this is a misinterpretation, for as the author shows, what is most probable is that an annual public dissection is being portrayed, to which the public was admitted, as to a theatre, upon payment of a small fee. The author also renders it highly probable that the painting was initiated at the suggestion of Dr. Tulp, and that each of the other figures in the painting paid their fee in order to have themselves portrayed. It was a nice idea. It is also clear that Rembrandt did not observe the actual anatomy, and that he was supplied with an illustration of the extensor tendons of the forearm and hand, which he erroneously superimposed upon the flexor surface of the forearm. This is quite clear to anyone with an elementary knowledge of human anatomy, and is further supported by the fact that the dissected forearm is somewhat out of proportion, being rather larger than it should be. But I am not sure of this latter criticism. A dissected limb is often much more massive in appearance than the undissected limb. So that here Rembrandt may have been sounder than his critics.

This is in every way a delightful book, with numerous illustrations, and nice fat footnotes at the back of the book, and beautifully produced in folio.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

MENTAL HEALTH MANPOWER TRENDS. By George W. Albee. (New York: Basic Books Inc., 1959, pp. 361. \$6.75.)

This book is the third in a series of monographs to be published by the Joint Commission Mental Illness and Health as a part of a National Mental Health Survey. It is a well documented study of major importance, dealing with a critical situation. The report will be of particular interest to all concerned with the planning and development of Mental Health programmes and treatment services.

The study is broadly based and clearly presented; much of the material was reported by the author in a previous study of manpower trends in psychiatry, psychology and social work. In this report Dr. Albee has enlarged upon the basic concepts presented in his previous work, and has emphasized the magnitude of the problem and the crippling effect of public indifference.

The material is introduced by Dr. J. R. Ewalt, the Director of the Joint Commission on Mental Illness and Health, who outlines the scope and content of the study. In the report, Dr. Albee presents the problem in general terms, and deals specifically with the current situation and future prospects for each of the professions directly related to mental health services. Each of these sections will be of special interest to the respective discipline. Separate chapters are also devoted to other professions and occupations related to mental health and mental illness. The work is concluded with chapters on "The Crisis in Education" and "Implications for the Future." Throughout the work the author has clearly indicated the basis for his opinions and conclusions, and the text is well supported by statistical data and an extensive bibliography.

ASEXUALIZATION: A Follow-up Study of 244 Cases. By Johan Bremer, M.D. (New York: Macmillan Company, 1959, pp. 357. \$5.00.)

This book is a follow-up study of 215 men and 28 women who were castrated because they were sex offenders. The report was made by Dr. Johan Bremer, medical superintendent of Gaustad Mental Hospital in Norway. Of the 215 men, 109 were classified as idiots, imbeciles, or morons, 53 as schizophrenics, 24 as psychopaths, 16 as sexual deviates, 10 as epileptics and 3 unspecified.

Following castration they were observed for periods varying from 10 months to more than 10 years. Four of them died from the operation. The data were obtained from hospital records, interviews with the castrates, their friends, and members of their families. Sixty-eight were castrated at their own request. Eighty castrations were compulsory, during the Nazi occupation. Thirty-seven were not brought before a court prior to castration. Of these, 13 were guilty of sex offenses against women, 10 were guilty of exhibitionism, 8 of sex offenses against young girls and only one

of sex offense against young boys. One hundred and forty-seven of the men were selected by psychiatrists as suitable for castration therapy. They were "so deteriorated or mentally underdeveloped that they had no conception of what castration involved." Of those who chose to be castrated "the dominating motive of the large majority was quite definitely to regain freedom." Individual cases are cited and the data regarding them is condensed in tabulated form.

It is evident that in many cases castration is regarded as a form of punishment and a considerable proportion of those who consented, afterwards regretted having agreed to the operation. The author is conservative in his conclusions regarding the value of castration. He says: "Castration is only of therapeutic significance in behavioural disturbances involving an urge for sexual relief. No general effect of pacification has been encountered . . . , no sedative influence on exaggerated affections, no harmonization of emotional life, no 'resocializing' influence on asocial or anti-social behaviour beyond the sexual sphere . . . castration has yielded poor results in schizophrenic and epileptic psychoses, and many complications of emotional origin have ensued in the psychopaths . . . the most satisfactory results were obtained in the case of the habitual sexual deviates, including the homosexuals and the oligophrenics." Aside from the misstatement in this last sentence there is little in the report of cases to support the impression that castration was therapeutic with habitual sexual deviates.

Twenty-seven of the 28 women were castrated by operation and one by x-ray. Two-thirds of them were under 25 when they were castrated and 11 were less than 20 years old. Thirteen were castrated for promiscuity and 14 for behavioural disorders. Nine of the 13 who were promiscuous have continued to be so. Ten were classified as psychopaths, 11 as idiots and imbeciles, 3 as schizophrenic and 3 as epileptic. The general conclusion by the author is: "The results of the legal castration of women seems so uncertain and poor that there is definitely doubt as to its justification."

Those who are interested in the indications for therapeutic castration of sex offenders with and without other manifestations of maladjustment may find considerable information in this book. The general impression given is that castration has no value as a form of punishment, and little if any value as a form of therapy.

GEORGE W. HENRY, M.D.,
Greenwich, Conn.

PREGNANCY, BIRTH AND ABORTION. By *Paul H. Gebhard, Wardell B. Pomeroy, Clyde E. Martin, and Cornelia V. Christenson.* (New York: Harper-Hoeber, 1958, pp. 282. \$6.00.)

Many of data utilized in this study were personally accumulated by the late Alfred C. Kinsey. Subsequent to his death in 1956 his colleagues have continued to compile and analyze data and this volume represents one of the results of their combined labors.

The authors state: "The data presented in the main body of this study represent a portion of the information secured from 5,293 white non-prison females who contributed their case histories to our study of human sexual behavior. In addition, . . . are data derived from 572 Negro non-prison females, plus 309 Negro women interviewed in prison, and 900 white women interviewed in prison. These data on women with prison experience seem to have no precedent in the literature."

All information was secured by detailed personal interviews, recorded in code, with assurances of complete anonymity. Of the white non-prison women 97% of the interviews occurred between the years 1940 to 1949. These subjects came almost exclusively from urban backgrounds and predominantly from the northeastern states. For the most part they represented women who had some interest in, and comprehended the value of, sex research, such as teachers, students, P.T.A. members, women's clubs, civic organizations, social workers and the staffs of hospitals and clinics. Protestants comprised 62% of the sample, Catholics 11%, and Jews 28%. Socio-economically this sample represents the upper 20% of the U. S. population.

The book begins with a study of the single woman and her pregnancy. This is broken down in its relation to age, marital status at interview, age at marriage, educational level, decade of birth, and degree of religious devoutness. Then the outcome of her pregnancy (live birth, spontaneous abortion or induced abortion) is studied in relation to the same factors. The pregnancy and outcome of pregnancy of the married woman are then analyzed in a similar manner. The remainder of the volume follows much the same pattern in studying the pregnancy and outcome of pregnancy of the previously married woman, the Negro woman, single and married, and the prison woman, white and Negro, single and married. The non-prison Negro woman and the prison woman are each accorded separate statistical treatment. The volume concludes with

a penetrating discussion of the many aspects of induced abortion and an appendix in which abortion problems in other countries (the Soviet Union, the Scandinavian countries, Japan, Latin America, etc.) are described in valuable detail.

The authors discuss their findings with an objectivity and a scientific restraint which is solidly rooted in the statistical evidence presented by the data at hand. They make no sweeping claims that their findings hold true for the population as a whole, but are frank to state that their conclusions apply primarily to the rather special group making up their sample.

Out of a wealth of data, the following material is of particular interest to psychiatrists:

1. Of the 754 previously married women (separated, divorced or widowed) of all educational levels, 3 out of 4 were found to continue having intercourse subsequent to the termination of the marriage. There were 157 post-marital conceptions, 79% of which ended in induced abortion. Comparing this with the single women who became pregnant premaritally, 75.8% of such pregnancies were terminated by an induced abortion.

2. The predicament of pregnancy in the previously married woman results in marriage in only 7% of cases, as compared to twice that figure among pre-marital pregnancies.

3. "The effect that the degree of religious devoutness has on sexual behavior (and its reproductive consequences) is strongest where religiously taboo behavior is involved."

4. For the lower educational level pre-marital pregnancies are frequent and induced abortions comparatively rare, whereas with the upper educational levels such pregnancies are less frequent but these pregnancies are more frequently terminated by induced abortion.

5. Out of a total of 1,067 induced abortions among the white non-prison women only 6.4% were legal abortions and these included operations for ectopic pregnancies.

6. The great majority of all induced abortions stem from pregnancies in marriage. The young married woman and the woman nearing the end of her reproductive life resort to induced abortion more commonly than does the middle group. Induced abortion is also commoner among married women who later become separated, divorced, or widowed.

7. Of the known agents responsible for the induction of illegal abortions among the white non-prison women, operation by physicians accounted for 91.2%.

8. Statistically this material gives no evidence of sterility or damage to orgasm capacity resulting from induced abortion. Unfavorable psychological sequelae were reported by 13.6% of the pre-marital group, 4.1% of the marital group and 5.4% of the previously married women.

Even if the findings in regard to induced abortion were characteristic only of the type of women included in this sample, they would be of great importance to psychiatrists. We know, however, from many other sources that the abortion problem is widespread throughout the country and that it involves all strata of society. This volume should lend support and courage to those who are endeavoring to bring more realism to bear upon the question of broadening the legal grounds for therapeutic abortion. To combat the high incidence of illegal abortion, the addition in legal codes of socio-economic factors to the already defined medical and psychiatric grounds for therapeutic abortion would bring the abortion problem under the control of the ethical medical profession—where it belongs.

ROBERT W. LAIDLAW, M.D.,
New York, N. Y.

JOHN DEWEY: *DICTIONARY OF EDUCATION*.
Edited by Ralph B. Winn. (New York: Philosophical Library, 1959, pp. ix + 150. \$3.75.)

John Dewey (1859-1952), commonly spoken of as America's foremost philosopher of our time, has been a controversial figure as all great thinkers must be. As he speaks or writes he is experimenting with the thought process, scrutinizing it in passage, and it may at times cost the listener or hasty reader an effort to follow. But the conclusion may be a brilliant summing up in a short pithy statement that sticks in the memory, an apothegm to be quoted.

There can hardly be a better introduction to the almost universal wisdom of Dewey than a book such as this, wherein the editor has collected from the writings of the philosopher and arranged in alphabetical order the subjects about which he has given formal expression of his views. These quotations vary in length from a line or two—"Prejudice is strengthened in influence, but hardly in value, by the number who share it"—to the 6 pages under the heading "School," representing passages from 7 sources.

In the logic of John Dewey every area of human experience and cognizance must be subject to the same kind of examination and

test that characterizes all scientific investigation. For fulness of knowledge there can be no reserved domain where the scientific method does not apply. Worthy knowledge is the product of intelligent experience and thinking and must lead to intelligent behavior and action. And if this is true of the individual it is even more significantly true of society. The philosophy of Dewey is therefore a social philosophy. And social philosophy and moral philosophy can not be strangers.

Santayana has said: "Morality is something natural. It arises and varies, not only psychologically but prescriptively and justly, with the nature of the creature whose morality it is." And again, "only a morality frankly relative to man's nature is worthy of man." And Dewey, whose thinking is not dissimilar, continues: "Morals is the most humane of all subjects. It is that which is closest to human nature; it is ineradicably empirical, not theological nor metaphysical, nor mathematical. . . . Moral science is not something with a separate province."

Dewey has been severely criticised as being responsible in considerable measure for the faults of his "progressive" education. Supporters on the other hand assert that juvenile indiscipline and other consequences of too much freedom in the early school years are attributable more to overzealous practitioners of progressive education than to the Master himself.

Perusal of the excerpts quoted under the headings School and Education give clearly Dewey's picture of school performance as it has been and as it should be. As they stand it is difficult to see how exception could be taken to these statements. Education is simply a function of the democratic process, indeed fundamental to it. "A democracy is more than a form of government, it is primarily a mode of associated living." And the keynote of this way of life as Dewey sees it is "the necessity for the participation of every mature human being in formation of the values that regulate the living of men together; which is necessary [for] both the general social welfare and the full development of human beings as individuals."

The key word in that sentence is presumably the word "mature." Maturity becomes a condition of satisfactory associated living. But maturity is not necessarily a consequence of the accumulation of years. And so we may have maturity in childhood or lack of it through all the decades. It is a quality that may not develop naturally and if acquired at all, may have to be learned the hard way, and

the school is the place to provide any possible guidance in that direction.

"Belief in equality is an element of the democratic credo. It is not, however, belief in equality of natural endowments. . . . In short, each one is equally an individual and entitled to equal opportunity of development of his own capacities, be they large or small in range."

But we find nothing in the text to suggest that freedom in the school room means freedom from guidance and such direction and control as needed for order and productive results.

However, at the 1959 annual meeting of the American Historical Association, as reported in the *New York Times*, Professor Lawrence Cremin of Columbia University Teachers College felt that there had been so much misunderstanding of the Dewey educational system that it was opportune to set the record straight. He stated that as early as the 1920's Dr. Dewey became increasingly critical of progressive education. "By 1938, the very year the Progressive Education Association reached its membership peak, Dr. Dewey could already perceive the ideological fragmentation destined to paralyze the movement. When the Association finally died in 1955, there were few mourners at the funeral."

In defence of Dewey as an educator Dr. Cremin spoke of "the distortions, the popular misconceptions and the gross caricatures that have long marked appraisals of Dewey," and he held that ignorance of the history of education was responsible for converting him into a "fictional figure in the policies of American education."

To properly review this book would be to quote more extensively than space allows. Keynotes of Dewey's philosophy are often expressed in a few incisive words which each must ponder for himself.

Here are two from My Pedagogic Creed (1897) "Education . . . is a process of living and not a preparation for future living." "Education is the fundamental method of social progress and reform."

Other apothegms: "The measure of civilization is the degree in which the method of cooperative intelligence replaces the method of brute conflict."

"Society is individuals-in-their-relations. An individual apart from social relations is a myth-or monstrosity."

"Natural rights and natural liberties exist only in the kingdom of mythological social zoology."

"Consciousness is only a very small and

shifting portion of experience."

"Skepticism that is not . . . a search is as much a personal indulgence as a dogmatism."

"There is no belief so settled as not to be exposed to further enquiry."

"Men may be brought by long habit to hug their chains."

"Man, a child in understanding of himself, has placed in his hands physical tools of incalculable power. He plays with them like a child."

"Manners are minor morals."

"The true means the verified and means nothing else."

"Values are as unstable as the forms of clouds."

C. B. F.

CURE DE SOMMEIL COLLECTIVE (Collective Sleep Treatment). By *Henri Faure*. (Paris : Maison & Cie, 1958, pp. 267. 2.500 fr.)

This book is the account of the personal experience of the author with prolonged sleep treatment in 142 patients (84 neurotics, 18 schizophrenics, 22 melancholics and 18 acute psychotic episodes), who concomitantly received group therapy. It is unique in the thoroughness with which the author presents individual observations, in the originality of of the organization and particularly in the consideration of psychotherapeutic processes during the sleep period. It is the first time that in a book on this subject the sequence of dreams and their psychological vicissitudes have been reported.

The author's set-up for sleep treatment consists of a totally separate ward from the rest of the hospital, where a group of patients spent an average of 20 days. The atmosphere of the section is geared toward providing a kind of "artificial paradise," where, in action or in phantasy, the patients experience a relatively complete gratification of their different needs. The sleep is induced with a combination of barbiturates and chlorpromazine. It is a relatively light sleep which allows the patients to communicate with each other and with the therapist who initiates a group therapy during the waking period.

The author describes behaviorally 4 stages during the sleep treatment, *i.e.* stage of adaptation, of regression, of tension and of reharmonization. He discusses the role of each stage in the process of sleep-cure, and in great detail gives the account of dream life of the individual during each period. Even though the emphasis is solely on the manifest content of dreams, the wealth of material and se-

quential descriptions are unique and most instructive. Each patient receives, concomitant with sleep-cure, individual and group psychotherapy. However, these psychotherapies are mainly supportive, aiming at the establishment of a positive transference and allowing the 4 stages of treatment to unfold themselves. The author maintains an "endogenous efficacy" for the sleep treatment, which transcends the psychotherapeutic function of the therapist and for this reason very little use, if any, of interpretation for the sake of uncovering, is made. This seems to be due to the general orientation of the author, which is eclectic. At times he seems to be oscillating between analytic, phenomenological, existential and physiological premises, and he employs a mixture of terms borrowed from these different disciplines. The author's main thesis is that the sleep-cure, based upon the premise of "abreaction," which is assumed to occur during oniric experiences.

It is regrettable that the section on therapeutic results is, in contrast to the other sections, relatively small, on the criteria of recovery and on the term "cure" which is constantly mentioned. In general the sleep-cure had no effect on chronic schizophrenics. The cases which showed complete recovery were among acute psychotic episodes (13 out of 18) and melancholias (11 out of 22). Out of 84 neurotic patients, 47 showed "frank stabilization." Taken in general these results appear equivocal; however, sleep-cure as envisaged by the author is not only a method of treatment but an investigational procedure as he so aptly demonstrates in his detailed case studies. As a whole the book is a must for all those who are interested in this area.

H. AZIMA, M.D.,

Assistant Prof. of Psychiatry,
McGill University, Montreal.

PSYCHOPHARMACOLOGY FRONTIERS. Edited by *Nathan S. Kline*. (Boston : Little, Brown Inc., 1959, pp. 533. \$10.00.)

It has become the vogue to publish uncritically as a book all the papers presented at a symposium. Sixty-five such papers presented at the Psychopharmacology Symposium of the International Congress at Zurich in 1957 are reprinted here. These deal primarily with Rauwolfia and phenothiazine derivatives but theories and experiments concerning monoamine oxidase inhibitors and other psychotropic compounds are well represented. In addition, the recorded discussion is appended and clarifies and expands immeasurably upon

these papers. Much of great value will be found here and it is this that makes this book more than the usual mere collection of papers. The section concerning clinical studies contains much repetition but in the sections on Specific Problems and Mode of Action one is amply repaid for time spent in close study of the thoughts expressed by some of the leading investigators in the world. Biochemical theories from Sweden, Germany, and Switzerland, carbohydrate and electrolyte studies from France, and electroencephalographic reports from Italy bring to us papers that we do not normally have readily available and translated for us. Prof. Delay's classification of these drugs help bring order out of an evergrowing plethora of compounds while Winkelman's and Ostrow's papers give one some understanding of and reason for using each type. Some papers deal with philosophic speculations while others include explicit statements as to the use of drugs in psychoanalysis, significance and treatment of side effects, and specific indications for each type of drug. Thus a study of the material in this book will provide one with some understanding of current theories of the mode of action of psychotropic drugs and repay the student through added confidence in their administration.

ROBERT R. SCHOPBACH, M.D.,
Henry Ford Hospital,
Detroit, Mich.

THE PROBLEM OF DELINQUENCY. By Sheldon Glueck. (Boston: Houghton-Mifflin Co., 1959, pp. 231. \$10.50.)

This book discusses the problem of juvenile delinquency in terms of "a set of materials which will reflect the intricacies of the problem and assist in training prospective prosecutors, judges, probation and parole officers, clinicians, social workers, and others in an appreciation of its ramifications and implications." There is little question that the author, who is the Roscoe Pound Professor of Law at Harvard University, has accomplished his expressed aim.

The book has been divided into 4 major parts. 1. Incidence and Causation; 2. The Juvenile Court and the Law; 3. Treatment; 4. Prevention of Delinquency. Each part is divided into various sub-sections and chapters covering a wealth of material, a great deal of which has appeared previously in law, psychiatric, sociological, psychological and other journals and books on the subject. In short, this book attempts to be a veritable encyclopaedia on the subject of delinquency.

Unfortunately, in spite of the thoroughness

of the coverage, much of the material contained in the sections on theory does not hold up, and the reader finds himself wishing that more attention had been paid to previous psychological and psychiatric research on the questions of delinquency, and that more consideration had been given to their findings. This objection is particularly disturbing because the author, as a law professor, is aware of the usual use of evidence, and yet many statements appear, particularly in the section on Incidence and Causation, which are generally unsubstantiated. This is not so much a criticism of the text as rather a re-emphasis of the need expressed by Professor Glueck himself for a more consistent binding of the theories on delinquency to scientific theories in other areas of science. This is specifically true in the areas of the biological and behavioral sciences.

The second section of the book on the Juvenile Court and the Law is excellently brought together. It contains, besides general histories of the juvenile court, the citations of various cases pointing up specific legal issues which have served to establish the legal precedents in the field, as well as a very thorough discussion of constitutional protections and various related problems. This section of the book can only be described as an outstanding contribution to our knowledge of juvenile delinquency and to forensic psychiatry and, as such, is certainly a major contribution.

The latter sections of the book are on Treatment and Prevention. The area of Treatment makes a definite attempt to report experiences in various situations, such as institutions, and there is an effort to gather evidence in various treatment methods. The emphasis is again, purposely, on the legal type of institutional treatment, *etc.* There is a section on psychotherapy, psychotherapeutic procedures and methods, which again we feel might have been more strongly emphasized, but generally speaking this area is quite adequate. The section on Prevention, of course, leaves much to be asked for, but they are the same things that are asked for generally by all workers in the field. Obviously, we cannot expect Professor Glueck to have the answers on how to prevent juvenile delinquency, but the suggestions he makes through the articles which he has included in his book are valuable and useful.

Generally speaking, we would say that this book has been a studious and worthwhile attempt at pulling together much of the available material. His contributors are drawn from all disciplines, including the legal profession,

psychiatrist, psychologists, sociologists, anthropologists. Professor Glueck's effort in bringing them together has been a valuable one. We would certainly say that this is a useful and necessary book for individuals faced with the problem of dealing with the juvenile delinquent.

Unfortunately, as is true of most encyclopaedic tomes, this book probably will not be read from cover to cover, but it will certainly remain one of the most important reference works in the field and will retain a long-term usefulness as such.

A PSYCHIATRIST WORKS WITH BLINDNESS. By Louis S. Cholden, M.D. (New York: American Foundation for the Blind, 1958, pp. 119. \$1.85.)

Two valuable and related achievements are to be credited to the American Foundation for the Blind as a result of their preparation of this handsome little volume of papers. They have published an appropriate memorial to the prematurely ended life and work of a brilliant and dedicated young psychiatrist whose service to the blind and to their organization was universally praised and appreciated. At the same time, they have also presented a collection of papers, the content of which provides a significant contribution to the understanding of the problems of rehabilitation not only of the blind but in other handicapped as well. This second accomplishment no doubt serves as an even more fitting memorial to the thoughts and efforts of a doctor and teacher who took up the challenge of work in this difficult field with enthusiasm, scientific discipline, originality of approach, and earnestness of purpose of a high order.

The role of a psychiatrist in the interdisciplinary efforts of an agency working with the handicapped has a number of facets of near equal importance and the papers in this volume indicate the awareness that Cholden had of these multiple responsibilities. Group therapy, for example, and the conduct and supervision of other forms of psychotherapy are only part of a program properly designed to meet the great range of problems involved in the rehabilitation of the handicapped. Liaison and cooperation with physicians and ophthalmologists are the concern of a paper on the psychiatric aspects of informing a patient of

blindness. An understanding of the patient's identity as a human being with particular personality patterns and a particular life situation at the moment is considered essential, in this and in every contact between doctor and patient. Certainly the traumatizing and regressing impact of serious illness, especially mutilation or loss of function will demand the keenest awareness of the dynamics of the total emotional situation as well as the awareness that the rehabilitation process in a catastrophic illness involves every aspect of the daily life of the individual. Counseling, medical services, education, questions of financial aid, vocational training, in a great range of taxing and complicated situations: the insights derived from this holistic approach are used to describe and illuminate the problems and techniques important in each phase of the rehabilitation effort.

Two papers merit particular note as excellent examples of the application of clinical and theoretical acumen to the special tasks confronting the worker with the blind. "Some Psychiatric Problems in the Rehabilitation of the Blind," contains a wealth of challenging information derived from a great deal of specialized clinical experience; "The Effects of Monetary Giving on Human Beings," reveals the extent of Cholden's helpful understanding of the difficulties involved in professional work with the blind on many levels. While it would be inappropriate to outline even the main ideas here, two quotes may serve as tempting bait to indicate the flavor and value of the content of all of this interesting book. "The principles of weaning, encouragement of independence, and maturation, characteristic of childhood development, are valid in the readjustment of the blind person. During this stage of maturation, working with well trained blind teachers is extremely valuable for identification and emulation remain excellent means of learning." "It seems peculiar, too, that some of the people having the same deep feeling for a client, will respond in exactly the opposite way (to those who over-identify). It is as though they cannot stand the pain of this identification and then they take the road which might say 'we have nothing in common, I have no sympathy or identification with you.'" This is similar to the blind person who will have absolutely nothing to do with any other blind person. It might be considered a rejection of identification.

HERBERT F. WALDHORN, M.D.,
New York 28, N. Y.

THE SOCIAL PSYCHOLOGY OF GROUPS. By John W. Thibaut and Harold H. Kelley. (New York: John Wiley and Sons, Inc., 1959, pp. 313. \$7.00.)

Thibaut and Kelley present a theoretical viewpoint about small group phenomena in which they systematically evolve a "point of view" that presents fresh and insightful ways of interrelating diverse statements about social behavior. Yet their work, as the authors realize, fails to meet many formal requirements of scientific theories. In both respects it reflects the current status of social psychology.

The query pursued throughout is, "How does social interaction influence behavior?" Here, they assign priority to essaying a clarification of dyadic interaction and its consequences for participants. Then they extend their analysis to more complex social relationships.

Their basic assumption is that most socially significant behavior is repeated only when somehow reinforced. Thus, in analyzing interaction, they center on the participants' possibilities for reciprocal control mediated by their ability to affect one another's "outcomes" (through rewards and reinforcements). Consequently, they construct "objective" reward-cost matrices in which *all* relevant variations in outcomes (rewards and costs) produced in the interaction are represented. Since individuals evaluate outcomes, 2 additional concepts are introduced to provide evaluative standards. The attractiveness of the dyad is determined by the person's comparison of experienced or anticipated outcomes with his "comparison level" which is influenced by *all* of the outcomes known to him. His dependency on the dyad is determined by his "comparison level for alternatives" which is the lowest level of outcomes a member will accept in the light of alternative possibilities.

The authors apply these concepts to understanding the dyad. Here they analyze the evolution of stable dyads, the extra and intra-interactional determinants of dyadic behavior and the determinants of members' attraction to and dependency on the dyad. They also present a careful analysis of norms and roles and the effects of varying task requirements and forced compliance.

Finally, they extend their concepts to encompass larger small groups. Now they discuss the effects of increased size on such social interdependencies as status, norms, power and control, roles and leadership.

This, then, is an analysis of a variety of social phenomena in the same limited set of

concepts and the use of these terms to organize apparently diverse research data. As such it is of real import. Thibaut and Kelley pursue their analysis forcefully and know their research literature. The content forms a refreshing antidote to writing that oversimplifies conformity, followership, leadership and the like.

As a scientific theory it suffers from the defects of its forefather, Lewin's "R-R immediate psychological field" theory. The explanatory statements are postdictive; unequivocal or negative evidence for the theory is virtually unobtainable. And properly so! The theoretical consequences of constructs demand that they be predictively related to empirical operations. This cannot be achieved if the authors insist upon the current definitions of their central concepts (all, known, *etc.*). Finally, while little is known about the systematic operation of social reinforcers, a much more explicitly sophisticated marriage between reinforcement learning and social psychology is required if the authors' approach is to become productive.

ROBERT C. JOYNER, PH.D.,
University of Toronto.

CONVULSIVE DISORDERS IN CHILDREN. By D. H. Chao, R. Druckman, and P. Kellaway. (Philadelphia: W. B. Saunders, 1958, pp. 151. \$6.00.)

This is a short treatise which Dr. Kellaway in the preface states "... is a revised version of a manual on convulsive disorders which the authors originally prepared for the use of residents in the Blue Bird Circle Children's Clinic. It is an attempt to provide a concise and simple review of diagnosis, treatment, and management of the convulsive disorders. . . ."

There is a "cataloguing" type of approach without much attempt being made to discuss the basic mechanisms involved or to give the reader a clear concept of the processes as a whole. It is much as if this were a manual for residents in medicine which listed the various etiologies and the signs and symptoms seen in congestive heart failure without any discussion of the physiology or how all of these fit into some reasonable or understandable pattern. Except for a very brief mention of some of the neuroanatomical basis of the various types of seizures, no discussion of or even references to the recent, important advances in neurophysiology or neurochemistry are given. All this may suffice for the busy general practitioner but represents unfortunate omissions for the specialist and particularly for the resident

in training. Too, probably insufficient attention is given to the psychological, psychiatric, and sociological aspects of epilepsy which are among the most important and most difficult problems in the care of the epileptic at the present time.

To commend the book are the chapters on "Massive Spasms," "Benign Febrile Convulsions," and "Breath-holding Attacks." These are topics not often discussed in other sources and are presented here concisely and well. The chapter on the "Management of Seizures" is also good. The "Role of Electroencephalography in the Diagnosis and Management of the Epilepsies" is rather thorough and would be, for the practitioner, a good introduction and appraisal of this laboratory method.

This book is not a definitive work on epilepsy nor apparently was that the intention of the authors. It can be recommended for the practitioner but, unfortunately, it lacks the depth and completeness required by the specialist or the resident in training for a neurological specialty.

W. J. FRIEDLANDER, M.D.,
Boston, Mass.

THE SURGEON AND THE CHILD. By Willis Potts.
(Philadelphia: W. B. Saunders Company,
1959, pp. 225. \$7.50.)

This is a wonderful contribution to the surgery of childhood. The title is most apt because it concerns Dr. Potts' own experience with paediatric surgery in the Children's Memorial Hospital in Chicago.

The contents are very readable and full of many apt expressions of the author's own. For instance, the chapter on portal hypertension is introduced by the statement "Portal hypertension in children is a tough problem." Comments such as this running through the entire book make it very readable and add to the interest. It reminds one of the classical treatise of Codman's on the shoulder in which the personality of the author shines through the whole book. It seems to me in this present world of super scientists we need more books with the individual touch to them such as this of Dr. Potts.

The whole approach to surgery in the child can be summed up in a few words from the beautiful chapter on the Heart of the Child, "Tell them in simple words why they have to go to the doctor, or the hospital, or why they have to have an operation and in most instances they will co-operate in a fashion that adults might well emulate. Faith and trust are completely unspoiled when children are

dealt with honestly. So little effort and so great the reward."

WILLIAM T. MUSTARD, M.D.,
Toronto, Ont.

BEHAVIORAL ANALYSIS: AN ANALYSIS OF CLINICAL OBSERVATIONS OF BEHAVIOR AS APPLIED TO MOTHER-NEWBORN RELATIONSHIPS. By David M. Levy, M.D. (Springfield, Ill.: Charles C Thomas, 1958, pp. 416. \$9.50.)

Is it possible to make a sufficient number of pertinent observations about a bit of raw behavioral data, abstracted from the total situation in which it has occurred, and arrive at reliable and significant inferences concerning the original situation yielding the data? The author attempts to do this, working with responses occurring in the early nursing situation. An observer stands at the foot of the bed and records, at a purely descriptive level, the succession of responses of both mother and infant, from the time the nurse brings the child into the room to the time she returns to take the child from the mother at the end of the feeding. Between 1943 and 1944, 15 mothers were observed on 2 or 3 such occasions in the neonatal week. Four other mothers who did not nurse their infants were included in the study.

The book is devoted to an analysis of the responses observed. The total situation was broken down into 3 major subdivisions: the greeting phase, the feeding phase, and the end phase. There were, in addition, a number of interval phases occurring at either the end phase or sometimes earlier, when nursing behavior ceased for a prolonged period of time. The running observational record was, in turn, broken down into more easily handled observational units, each unit containing a separate maternal response.

The author's concern was with the question of whether or not a statement could be made concerning an attitude, specifically maternal attitude, with regard to both its presence or absence and its quantitative variation among the group of mothers, from an analysis of observational data alone. The author believes that ultimately this could be done, but he found it useful, at least in the initial stages of the investigation, to make use of a temporary expedient in order to obtain a preliminary ranking of the mothers in regard to maternal attitude. A questionnaire, previously tested to reveal maternal feeling, was given to the mothers, and provided a clinical measure of the most and least maternal mothers in the

group. It soon became apparent that the problem of establishing adequate criteria for a comparison of behavioral responses led in two directions; first, the examination of the situation in which the response was occurring and second, the behavior of the infants in relation to the maternal response under scrutiny. The responses obtained in each phase were analyzed as independent variables, according to number and variety; as variables dependent upon the situation, the situation defined as a specific set of conditions under which patterns can be compared; and finally, as variables dependent upon the person; as, for example, the responses of the same mother on different neonatal days.

When this isolated segment of relational behavior is so scrutinized, a myriad number of exploratory possibilities appear to be imbedded in the data themselves. When this is pursued with ingenuity, as well as with rigorous honesty and a scrupulous avoidance of any loose, general, or unwarranted assumptions, the result is a series of exciting developmental sequences, during which time a gradual shift occurs from a reliance on clinical measures and opinion, to a ranking of the mothers in regard to maternal attitude, based solely on the data themselves. Were the author only concerned with the specific questions raised about maternal attitude, one might well wonder whether the conclusions reached concerning the ranking of the mothers warranted the elaborate, patient, tenacious working-over of the data. Viewed as the prototype of a method possibly applicable to many other problems in behavioral science, and as a technique for the examination of behavioral responses at an objective level and removed from the inferential and motivational biases of the observer, the contribution is both original and stimulating.

The task of the reader is a somewhat exacting one, despite the absence of jargon of either a psychiatric or a statistical variety. The analysis is, at times, so intricately detailed that the reader must be prepared to maintain a running familiarity with the raw data as well as keep pace of the analysis as it proceeds. These tasks would be somewhat easier were it not for an uncommonly large number of typographical errors and editorial oversights. These included spelling errors (pp. 147, 190, 223, 237, 243, 254, 287, 273, and 276), instances in which footnotes were incomplete or absent (pp. 141, 191, and 195), instances in which references to tables appeared mistaken or con-

fusing (pp. 143, 153, and 182), and an instance in which a part of a sentence was reduplicated (p. 249).

The reading of this book is an experience in the application of logical inference to carefully-distilled observational data. The book will probably be of greatest interest to research workers in the behavioral sciences. At a more general level, it spells out an important lesson for all psychiatrists by establishing a basis for a deeper appreciation of observational data in a field where interpretive and motivational analyses have so long held the spotlight.

MONTAGUE ULLMAN, M.D.,
New York, N. Y.

PSYCHOLOGY: A STUDY OF A SCIENCE. Study I. Conceptual and Systematic. Vol. I. Sensory, Perceptual and Physiological Formulations. Edited by Sigmund Koch. (New York: McGraw-Hill, 1959, pp. 710. \$9.75.)

This is the first of a series of a projected 7 volumes which will involve 80 contributors. Study II will be entitled, "Empirical Substructure and Relations with Other Sciences," and Study III, "Psychology and the Human Agent." Most of the papers in Study I are highly technical as may be gathered from such chapter headings as: "Three Auditory Theories," "Color Theory," "Quantum Theory of Light and the Psychophysiology of Vision," "Theory of Stereoscopic Vision," etc. Probably of greatest interest to psychiatrists are the chapters by Hebb, "A Neurophysiological Theory," and by Morgan, "Physiological Theory of Drive." In the latter, in particular, the author has brought together experimental evidence to support a "central motivated state" in contrast to peripheral theories. The central theory, in brief, proposes that drives may be aroused and abated by states in the central nervous system rather than solely by stimulation of receptor organs. Of special interest to the author are the states that lead to behavior involving hunger, thirst, and sex. Alteration in these states is produced by changes in electrolyte balance, hormones and activity in the reticular system.

The intent of the whole series is to survey the status of psychology as a science. Probably later volumes will reveal material of more direct relevance to psychiatry.

P. E. HUSTON, M.D.,
Iowa City.

FLANDERS DUNBAR

IN MEMORIAM

FLANDERS DUNBAR

1902-1959

Flanders Dunbar was not a conventional physician who followed the traditional career of her profession. Her interests were broad and comprehensive, extending from literature, religion, psychiatry, psychoanalysis and psychology, to internal medicine.

Born in 1902, the daughter of a physicist and mathematician, her career was a true reflection of the universality of her interests. After obtaining a B.D. degree at Union Theological Seminary, she obtained her M.D. at Yale and undertook clinical research at the Worcester State Hospital. She continued her studies at New Haven Hospital and Bellevue, then at the Psychiatric-Neurological Hospital in Vienna and at Burghölzli. She received her Med. Sc.D. degree from Columbia University.

Dunbar was a pioneer in widening the field of the medical sciences through the study of the influence of emotional factors upon diseases. She was a woman of great intuition and imagination, disciplined in the philosophy of science. All this made her predestined to become one of the most outstanding physicians among those who introduced a new emphasis into medicine, the psychosomatic approach to the study and treatment of chronically ill patients. Attracted by the ancient body-mind dilemma, she cut across the traditional philosophical meditations and attacked this eternal problem which taunted medical men, philosophers and religious leaders since antiquity until our own times, in the Hippocratic spirit of unprejudiced bedside observation. She made her findings available to others in a steady flow of careful and well-organized publications. Her comprehensive studies of serial admissions of unselected patients at the Presbyterian Hospital in New York are classical contributions to modern medicine. She observed and described the totality of the patients, their physical, psychological and environmental conditions, and described personali-

ty profiles characteristically found in different diseases. Under the influence of other workers' findings, she modified her theoretical concepts and accepted the view that organic syndromes correlate with circumscribed psychodynamic constellations rather than global personality traits. One of the most impressive among these psychosomatic studies is the discovery of the accident-prone personality. This finding came about as truly novel discoveries often do—unexpectedly. She used surgical patients, victims of accidents, as a control group to compare their psychology with patients suffering from chronic ailments. This group which she expected to show no specific emotional features turned out to be a psychologically well-defined group.

Apart from her original contributions to psychosomatic medicine, she compiled a monumental reference book, *Emotions and Bodily Changes*, which in serial editions kept pace with this rapidly growing field. This volume gave research workers invaluable help and has remained a standard publication of historical significance.

Her general influence upon the development of medical thought and research was outstanding. With the collaboration of a small group of physicians and with the help of Frank Fremont-Smith of the Josiah Macy, Jr. Foundation, who shared her conviction about the significant role of emotional factors in organic diseases, she founded at first the *Journal of Psychosomatic Medicine* and later the American Psychosomatic Society. It can justly be said that no single person was more effective than she in the organization of the psychosomatic approach in modern medicine.

Those of us who from the beginning collaborated with her in this venture had opportunity to become acquainted with her, not only as a medical pioneer but as a person as well. Her all-absorbing devotion to her work served as an inspiration for all of

us. No one could, however, keep pace with her prodigious working habits. Even when travelling, she incessantly dictated her ideas to her secretary, read every publication on her field, corrected manuscripts and discussed and formed editorial policies. At the editorial meetings of the new Journal held in regular intervals at her home, she set a model for effectively organizing a medical journal and maintaining its standards. She was a rare combination of a productive and original theoretician, clinical observer, therapist and organizer. As many pioneers, she was subjected to criticism from those who resisted her insistence upon consider-

ing psychological factors as seriously as somatic ones in organic disease—an attitude that was still alien to the prevailing mechanistic physico-chemical orientation. Because her devotion to research was so much greater than her personal ambitions, she would take these objections as well as the criticisms of her psychosomatic colleagues without personal resentment and was always ready to revise her formulations by new evidence. Not only psychiatry, but the whole of medicine lost in her a pathfinder of unusual stature.

Franz Alexander

GEORGE NEELY RAINES

1908-1959

George Raines' death leaves areas of loss which will have differing significance to the many who knew him. Those who knew Dr. Raines largely by his professional attainments will point to the end in mid-career of a nationally known leader who stood for progressive psychiatry. His intimate friends will keenly miss a man of feeling who knew how to live the full life. Still others would point to the wide range of his interests. Perhaps those who knew him as a Chief Examiner at the Boards would agree his loss was most typified in many ways by the silencing of the Mosun's pipe which paced his section, rich with significance for those who could read its meaning.

George Neely Raines, retired Captain U. S. Navy Medical Corps, age 51, died September 16, 1959 at the U. S. Naval Hospital, Bethesda, Maryland, following a relatively brief illness caused by metastases from a bronchogenic carcinoma, first recognized about a year earlier as a solitary nodule on a routine annual chest x-ray. His death occurred, as so often, in an otherwise robust, healthy individual in his most productive years.

Dr. Raines was born in Jackson, Mississippi in 1908, the youngest of 3 children of a local merchant. It is said his father would have preferred him to study dentistry and was surprised at his choice of psychiatry.

George was ever practical as a psychiatrist, and undoubtedly acquired much of his hard headed realism from his family background. A newspaper group picture of his third grade class shows an alert youth somewhat smaller than the average of the class. It is reported that he had a 99.5 average on graduation from high school, the highest in the history of the school. He graduated from Ole Miss. in 1928 with a B.S. degree at the age of 20. He obtained a Bachelor of Medicine degree from Northwestern in 1931 after completing one year of internship at the U. S. Naval Hospital, Mare Island, California.

A love for the Navy developed which contributed to a disciplined thinking and intolerance for any mediocre performance. His Navy career was outstandingly successful. He was commissioned Lieutenant (j.g.) in the Medical Corps of the Navy June 26, 1930 and advanced to the rank of Captain. March 10, 1945. Captain Raines served aboard the *USS Idaho*, *USS Saratoga*, *USS Lexington*, and on destroyers as a general medical officer. He began a brilliant career in psychiatry while in the Navy, first serving as assistant to the Naval Unit at St. Elizabeths Hospital. He served as Assistant Chief of Neuropsychiatry at the Old Naval Hospital, Washington, D. C.; subsequently as Chief of Neuropsychiatry at the U. S. Naval Hospital, Portsmouth, Virginia, from

1943 to 1945 ; and Chief of Neuropsychiatry at the U. S. Naval Hospital, Bethesda, Maryland from 1945 to 1950. From 1950 to 1953 and again from 1955 to 1958 he was Head, Neuropsychiatry Branch, Bureau of Medicine and Surgery, Navy Department. From 1953 to 1955 he served as Executive Officer and Commanding Officer of the U. S. Naval Hospital, Portsmouth, Virginia. He was retired from the Navy May 1, 1959. A Navy release states "Dr. Raines' singular accomplishments in psychiatry contributed tremendously to the growth and development of naval psychiatry."

Many of his closest friendships were those who served with him in the Navy. He inspired utmost loyalty from his staff. The term "feathermerchants" will be understood by his close friends of this period, defining again his absolute loyalty and utter rejection of the false or hypocritical. His Navy friends will remember fondly the story he told of the ceremonial reception when piped aboard his first ship in full dress as a Junior Medical Officer. The decision to apply for temporary disability status, enforced by his illness, was perhaps the hardest decision Dr. Raines had to make. This did not occur until one year after hospitalization and he was to die only four months later.

There is so much to say about the peaks of success Dr. Raines attained in the field of psychiatry that summarizing is difficult. Above all I would emphasize his talent as a teacher. As Director of the Department and Professor of Psychiatry at the Georgetown University Medical School in Washington, D. C., from 1948 to the time of his death, he brought to a climax an association of many years with this school. He brought to Georgetown an able staff, greatly expanding the department, establishing residency training, and developing the teaching of psychiatry to a parity with the other major departments in the school. At the student level the program equaled or surpassed in curriculum hours that of all other medical schools. His inspiring talent led to a prodigious effort on the part of his staff and his pioneering foresight permitted the development of maximal supervised therapy responsibility provided to the student.

He was an examiner on the American Board of Psychiatry and Neurology for a

number of years and was President of the American Board in 1956. He was active with committees of both the American Psychiatric Association and the American Medical Association. He was Chairman of the Committee on Nomenclature and Statistics of the APA, a committee which developed the Standard Psychiatric Nomenclature. In 1954 he was a member of the Council of the APA. He assisted in the early development of the Group for the Advancement of Psychiatry. He served as Special Consultant to the Surgeon General of the U. S. Public Health Service and was a frequent participant in meetings which developed policy of the American Psychiatric Association.

Dr. Raines' professional experience included didactic analysis and training with the Washington-Baltimore Psychoanalytic Institute in 1946. His approach was broad and encompassed a profound understanding of what is best described as dynamic psychiatry, including an extensive foundation in "basic" psychiatry and neurology. He had a truly remarkable capacity to keep abreast of new developments, as was manifest in his teaching and in his private practice. His publications cover a wide range of interests, administrative, clinical, and teaching experience, again with emphasis on basic psychiatry, with earlier studies in neurophysiology.

The list of professional organizations of which Dr. Raines was a member includes Phi Chi medical and Sigma Chi college fraternities, American Medical Association, American Psychiatric Association, American College of Physicians, American Neurology Association, Association for Research in Nervous and Mental Diseases, American Psychopathological Association, District of Columbia Medical Society, Washington Psychiatric Society, Washington Psychoanalytic Society, and Medical Society of St. Elizabeths Hospital. He was in *Who's Who*.

In closing I would like to turn again to Dr. Raines as a humanist, family man and friend. Above all George Raines will be remembered as a warm friend and bosom companion. The warmth and humor he experienced in life were richly conveyed to others. His own zest for living was felt

by those close to him. This trait enlivened personal contacts, committee groups, even large meetings. There was also a seriousness of purpose and capacity to sense the essence, often the irony, of a situation. His sense of the fun of living was manifest in an early interest in jazz. Many did not know that George was a jazz buff, or that he was a drummer and played in a Dixieland style band in college days. To the end he delighted in an opportunity to get back to New Orleans to hear again what is there today of the jazz tradition. He had a knack for being where things were happening. A story he would tell more intimate friends might be told now. George had accidentally sustained a slight scalp wound and happened to be on his way home and in the immediate vicinity of the St. Valentine day massacre in Chicago. The Chicago police picked him up and for a while thought they had their solution to the crime.

I have emphasized this side of Dr. Raines' character because his many friends will

remember most intimately and will miss always a companion no one else can quite replace. Dr. Raines and Kate St. Clair married in Mississippi. There are two children. A daughter, Mary Anne Goslen is now a resident of Greensboro, North Carolina. A son, Lt. (j.g.) George N. Raines, Jr., is in the Navy assigned to underwater demolition work and presently serving at Coronado, California.

It would be an error to close without reference to a philosophical trend Dr. Raines seldom made manifest except to those who knew him most intimately. He was deeply religious, and for a number of years had considered becoming a Roman Catholic. It was a step he took with finality at a time during his illness when he was certain of his intention. Thus in death as in life George Raines was a man of deep conviction and had the good fortune to see his most cherished goals realized.

John D. Schultz, M.D.

HUMAN ECOLOGY, DISEASE, AND SCHIZOPHRENIA¹

LORING F. CHAPMAN, Ph.D., LAWRENCE E. HINKLE, JR., M.D.,
AND HAROLD G. WOLFF, M.D.²

The thesis herein offered is that when inappropriate in kind or amount, the adaptive reactions evoked in an individual in response to threat can result in impairment of organ function and in some instances to tissue damage. Evidence will be cited to show that the functional capacity of the brain also may be restricted following prolonged unsuccessful attempts at adaptation. A further elaboration of the thesis is that the reduction in overall adaptive capacity stemming from this impaired functioning of the brain is relevant to serious disturbance of mood, thought, and behavior, including the clinical syndrome of schizophrenia.

HUMAN ECOLOGY

These studies have been carried out within the framework of a concept of human ecology that focusses on the interactions between the individual human subject and his environment (1, 2, 3, 4). The attitude of the naturalist is epitomized in the discipline of ecology, dealing as it does with interrelations of organisms and their environment. Those biologists who have taken the broad view of ecology have seen it as embracing the study of any of the pertinent features of the relationship between living organisms and their natural habitat. The ecologist may be properly interested in any aspect of the environment to which the organism must adapt, with the adaptive mechanisms within the organism and the anatomical structures upon which these are based, as well as in the behavior of whole organisms, and that of the colonies and societies which these organisms develop.

Early in the 20th century the botanist, J. W. Bews (7), suggested that the ecological discipline might be applied profitably to the study of mankind. He saw that those who would deal with problems of human ecology must be prepared to make use of the concepts, knowledge and techniques of many scientific disciplines. To him human ecology is a way of looking at man and of asking questions about him that would be most pertinent to understanding man as a living, constantly adapting organism, never apart from the milieu in which he exists, and constantly interacting with it. Thus, in so far as possible, men would be studied in their natural habitat, behaving as men behave, in the full range of their humanity. This concept has also been evolving independently with us, as a result of our own studies (6, 7, 8, 9, 10, 11, 12, 13).

Such an orientation does not impose the necessity for an intensive investigation of all the factors involved. Indeed, it does not even require the concurrent operation of a "team" of workers with different disciplines, although sometimes necessarily such workers are turned to for specific information. Human ecology is, first of all, the study of man in his setting. Singularly important in this setting are other men, and central to the problem of his health and well-being are his relations to them.

A THEORY OF DISEASE

Claude Bernard (14), the great French biologist of the mid-19th century, was among the first to see disease as the outcome of attempts at adaptation—attempts which though appropriate in kind, are faulty in amount. Since the defensive response in its intensity can be more destructive than the original assault, an individual may be damaged gravely through the wrong magnitude of his defensive reactions. For instance, the presence of microorganisms in the lung calls forth cellular and humoral reactions that counter invasion, and usually do so effec-

¹ Read at the 114th Annual Meeting of the American Psychiatric Association, San Francisco, Calif., May 12-16, 1958. Submitted, revised, for publication Apr. 22, 1960. These studies were supported in part by grants from the Society for the Investigation of Human Ecology.

² From the Study Program in Human Health and the Ecology of Man, and the Departments of Medicine (Neurology) and Psychiatry, The New York Hospital-Cornell Medical Center, New York, N. Y.

tively. Yet their magnitude when excessive can lead to congestion of the lungs, and to pneumonia. This inappropriate adaptive response becomes especially ominous for the individual when tissue is already involved in a long standing over-reaction, as in chronic lung disease.

Claude Bernard's penetrating definition of disease as resulting from the wrong magnitude of attempts at adaptation, deals mainly with primitive biologic levels of reaction. His observations are also true of man, but disease in humans has a more complex meaning because of man's highly developed nervous system.

The unity of mind and body makes man react adaptively or defensively not only to damaging trauma or microbial forces, but also to threats and symbols of danger. Under circumstances perceived as threatening, he inappropriately may evoke primitive metabolic or reproductive patterns that ordinarily serve to maintain the body and the stock. His adaptive and protective patterns are limited in number, and the form of the reaction depends more on the individual's nature and past experience than upon the particular noxious factor evoking it. Since certain bodily and behavioral patterns are called upon to attain goals that can never be attained through their use, such inappropriate reactions are indefinitely protracted. Functions which are usually phasic become continuous. The tissues involved are pressed beyond their limits. Devices that ordinarily serve to protect the body then destroy tissue.

THE THREATENING NATURE OF CHANGING CIRCUMSTANCES

Among the many circumstances perceived as threatening, one of the most threatening is change itself. Rapid and violent social change, by disrupting established relationships, constitutes a serious threat.

Is there evidence that disruptive changes may be relevant to infectious processes? The occurrence of epidemics and increased morbidity from infections among human populations during periods of major change, readjustment and mass dislocation is well known. High mortality from tuberculosis has been associated with increased industrialization during the 19th and 20th centuries

and the resulting migrations from rural to urban life and from one country to another (6, 15). The high mortality has usually been considered the result of exposure to cold and rain, lack of food, excessive effort, crowding, and contact of a migratory population with new and fresh sources of infections to which they had developed insufficient immunity. However, the explanation is probably more complex. For example, in a given society, mortality from tuberculosis has been found to be closely tied to the period in the history of a culture when the use of industrial machines becomes widespread. Mortality reaches its peak about 10 to 20 years after industrialization and thereafter falls off rapidly.

Observations of this kind, led René Dubos (16) the distinguished microbiologist, to conclude:

There is reason to wonder whether any microorganism cannot become the cause of disease if suitable conditions are provided for it. Thus there are many circumstances, some of which are of common occurrence in human medicine, where the physical, chemical, physiological, and probably psychological factors which affect the host, play far more decisive parts in the causation of disease than does the presence of this or that microorganism.

The incidence of hyperthyroidism in Norway increased 100% during the first year of World War II when that country was invaded (21). Other basic endocrine disorders are evident during periods of chaos. Impairment of sexual function with accompanying amenorrhea occurred in nearly all women after interment in the Nazi prison camp of Theresienstadt during World War II and in most of the other camps from which reports are available (18).

STUDIES OF ILLNESS INCIDENCE IN LARGE POPULATIONS

A large-scale study of men and women in the context of their environment, and its relationship to their health, has been made in this laboratory (19, 20, 21, 22). The life stories of more than 500 ostensibly healthy people were analyzed and shorter segments of the lives, of approximately 3,000 observed. These included not only native American, but also homogeneous groups of

foreign-born persons with an entirely different cultural tradition.

Illness was not spread evenly through these populations. In fact, during the prime of life, about one quarter of the individuals accounted for more than one half the episodes of illness. In some groups there were more than 20 times as many episodes of disabling illness in the "least healthy" members as there were in the "most healthy" members. Some individuals had as little as 20 days of absence from work because of illness in 20 years, and others more than 1,300 days in that length of time.

The persons with the greatest number of illnesses had a wide variety of illnesses. Those who experienced a great deal of illness not only had had many minor, but often numerous major disorders of medical, surgical, and psychiatric nature, including infections, injuries, new growth, and serious disturbances in mood, thought, and behavior.

Episodes of illness often clustered during limited periods of time; that is, there might be many episodes in one or more particular years, contiguous with other periods during which few or no illnesses occurred. These periods of high illness incidence corresponded with the periods perceived by the individual as the most threatening.

Within a given population, when the "most healthy" were compared with those who experienced the greatest amount of illness it was evident that physical hardships, geographic dislocation, exposure to infection, rapid social change, and interpersonal problems occurred with almost equal frequency in their lives. There were, however, differences in the two groups. Those most often ill, in contrast to those least often ill, usually viewed their lives as having been difficult and unsatisfactory. They were more inflexibly oriented toward goals, duties, responsibilities. They reacted sharply to events that confronted them. Typically they were in conflict about pursuing their own ends and ambitions on the one hand, and on the other acting responsibly and according to early learned principles about wives, children, parents and friends. They were "concerned" people, who "took things seriously." Most of them were very much aware of their emotional difficulties and their poor

adjustment in interpersonal relations, and many complained about them. They were anxious, self-absorbed, "turned in," unduly sensitive people who sought much support and encouragement.

In contrast, those who were rarely ill often viewed their lives as having been relatively satisfactory. They came of more stable and complete families, capable of and willing to lend more support. In general they viewed themselves as having had preferred sibling positions, good marriages, and rewarding careers.

It was evident that the relationship between the occurrence of illness and "difficult life situations," is not solely with the difficulty of the situation as seen by a neutral observer but is closely related to the amount of threat in the situation *as perceived by the person who experiences it.*

Diseases in which the relationship between symptomatology and the individual's perception of his environmental setting can be seen especially readily have been termed "psychosomatic." But these studies do not support the view that there is a special category of disease to be designated by this term. With the exception of those instances of grave inborn functional or structural errors that early in life narrowly limit the range of adaptability, either at its simple biological or the more complex neurobiological level, it was seen that symptomatic illnesses of all kinds arise in and are remarkably influenced by environmental circumstances perceived by the individual as threatening.

Disease is the end result of so many interacting factors that the concept of the "cause" of disease in a specific instance becomes almost unmanageable. While it is apparent that inappropriate adaptive responses to threat contribute especially heavily to the initiation of certain syndromes, such as gastrointestinal ulceration or vascular headache for example, the data of these studies also indicate that it is erroneous to establish a separate category of disease in which these inappropriate responses are the primary or sole etiologic factors. Rather, inappropriate adaptive responses mediated through the central nervous system are implicated to some degree in disease of many categories including infectious, degenera-

tive, neoplastic, and psychiatric. Reactions evoked during unsuccessful attempts at adaptation, even when integrated at high levels of brain function and involving widespread physical and chemical processes, are not necessarily accompanied by outward evidence of emotional disturbances or even by the individual's awareness of an altered feeling state. Bodily illness, on the one hand, and disturbance of mood, thought, and behavior, on the other, are thus best seen not as causally related, but as each being a component of the individual's total response to his internal and external environment.

What reference have these points to longevity and to death? There are hints from other sources that years of life can be pressed out of man by catastrophe or prolonged duress. Physicians often see sudden and unexplainable death come to those who are overwhelmed or filled with despair. There is evidence that "bone pointing," "hexing" and excommunication of transgressors of tribal mores may remarkably shorten life if not immediately kill a man(23, 24).

ECOLOGICAL IMBALANCE, IMPAIRED ORGAN FUNCTION AND TISSUE DAMAGE IN MAN

Studies from this laboratory have demonstrated that many of the body's organs become more readily damaged during or following periods perceived by the individual as threatening: vasodilatation, edema, diapedesis, hemorrhage, erosion, increased friability of tissue, lowered pain threshold and impaired organ function have been observed in the skin(25), nose, airways(26), stomach(27, 28), colon(29), bladder(30, 31), vagina(32), and in the subcutaneous tissues of the scalp(33). These changes could be induced or terminated rapidly by appropriate alteration of the environment, as by interviews which augmented or decreased the perception of threat.

Over the years one organ or system of organs after the other has been studied in persons functioning in the context of their homes and work environment. For example, in a setting which some individuals perceive as presenting a threat of a certain type, the mucous membrane lining of the stomach becomes intensely engorged, its rate of acid secretion greatly accelerated,

and its rhythmic contractions augmented. This is the stomach pattern of a man preparing to eat a meal. Under circumstances that call for entirely different reactions of aggression or striking in anger, the individual has inappropriately evoked an eating pattern. Similarly, the crying-out anger pattern, with hunger—one of the earliest to appear in infancy—may reassert itself in later life during periods of deprivation or repression of longing for emotional support. Since this displacement behavior seen in the eating patterns cannot satisfy such longings, the gastric activity is excessively prolonged and the lining of the stomach may digest itself. Peptic ulceration may ensue(8, 27, 28).

In studies of the large bowel it has been observed that in those who perceive themselves as threatened in a given way, the mucous membranes become engorged and motility and secretion augmented. This is the pattern of ejection, one that could be used in ridding the organism of materials inadvertently taken in, yet it is evoked inappropriately to help the man rid himself of an unattractive interpersonal problem that cannot be dealt with in this way. Abnormal secretions and the by-products of breakdown may then destroy the lining of the bowel, resulting in ulcerative colitis(29).

Observations of the mucous membranes of the nose, upper airways and lungs have shown that circumstances which the individual perceives as threatening may result in engorgement of the mucosae, increase in secretion of mucous, contraction of smooth muscle of the airways, and even spasm of skeletal muscle. Also, the eosinophil and neutrophil cellular content of nasal secretions increases and there is an increase in the number of eosinophils in the circulating blood. The eyes may tear and close. This is the pattern properly evoked by dangerous gases, fumes, dust, and microorganisms and it serves well to shut out, neutralize and wash away. Yet it is also used by some people in dealing with an offensive man-to-man situation. Because of excessive and inappropriate use, the reaction may trigger chronic infection, chronic obstructive disease, and asthma(26). Alterations in the chemical make-up of the secretions within

the lungs may end in tuberculosis by affording an opportunity for organisms to reproduce that otherwise would die.

Under circumstances that threaten an individual's fulfillment of his responsibilities and are met by heightened vigilance, the blood vessels about the head may constrict and the great sheets of muscle of the head and neck go into painful cramp (34-37).

Many skin disorders arise under threatening circumstances because of inappropriate responses of the blood vessels and unusual secretions in the skin (25, 38, 39). Under like conditions, the kidney may be damaged because it gets too little blood, with great outpouring or retention of water and salt (40-45). So also the heart and blood vessels of the body may overwork and contract excessively as though the individual were stopping a mortal hemorrhage, or facing a crisis of fight or flight—when, as a matter of fact, he may be sitting inertly in a chair (46, 47).

When a person feels his prestige endangered, the glands of internal secretion—the pituitary, the thyroid, and the adrenals—may respond as though his very existence were in jeopardy, as by starvation, or by the sudden unusual demands of very low temperature or violent action (48, 49).

Contraction of the muscles of the extremities and back, inappropriately responding to threatening circumstances by preparing the individual for prompt action that never takes place, can cause severe cramps and aches (50).

No organ or part of the body is spared in these inappropriate responses that are so suggestive of the displacement behavior patterns of rats (51) and gulls (52) and fish (53) studied by the animal behaviorists. Yet not all reactions that end as disease in man can be seen as "displacement" patterns. Migraine headache which results from the painful dilatation of the blood vessels of the head coupled with a local sterile inflammatory reaction often occurs not during stressful periods but after their termination (34, 54).

Distention of cranial arteries is a significant factor in vascular headache of the migraine type. Also, it is evident that the accumulation of a pain threshold lowering substance in the walls of these arteries as

well as in the adjacent perivascular, areolar and supporting tissues, is an essential feature of the headache attack. Accordingly, attempts were made (55) to define the properties of perfusate collected during migraine attacks from subsurface tissues in the region of the temporal and frontal vessels of the head. The specimens collected from the head during headache attacks predictably contained a substance that could be distinguished from serotonin, ATP, substance P, acetylcholine, and histamine although these and other substances could also be present. This agent relaxed isolated rat duodenum, contracted rat uterus and depressed the blood pressure of the rat. The substance has many of the properties of bradykinin, but when analyzed quantitatively using several assay procedures it was evident that it is not identical with bradykinin, but closely resembles the vasodilator polypeptide "neurokinin" that has been found in this laboratory (56) to be present in perfusate collected during the onset of axon reflex "flare" in the skin. The amount of active agent found in the specimens paralleled the intensity of the headache attack. The increased content of polypeptide found locally and the relevant protease could account for many of the features of vascular headache of the migraine type: the polypeptide is an extremely powerful vasodilator, it induces pain and lowers pain threshold when reinjected intradermally, and it increases capillary permeability. Vascular headache of the migraine type thus can be seen as the consequence of an excessive accumulation of a neurogenic agent implicated in local vasomotor control, resulting in a local sterile inflammatory reaction.

THE NERVOUS SYSTEM AND PRIMITIVE BIOLOGICAL REACTIONS

A recent series of investigations (38, 52, 58, 59) has focussed on ways in which activity of the nervous system can influence inflammatory reactions and vulnerability to injury. It was demonstrated that peripheral nerve action can result in alterations that both damage the tissue subserved and alter the reaction to injury. Thus, significantly more skin damage occurred in the "flare zone" of an axon reflex than in adjacent

control areas in response to similar amounts of noxious stimulation. Also, immersion of the lower extremities in water at 43° C. resulted in widespread vasodilatation and a transient lowering of the pain threshold and heightened tissue vulnerability as measured on the hand and thorax.

Following standard amounts of noxious stimulation on the forearm during hypnosis, increased inflammatory reaction and tissue damage was observed in subjects to whom repeated and forceful suggestions had been made that the forearm was tender, painful and injured. Diminished tissue damage was observed when the subject was told his forearm was "anesthetic." Recordings of finger pulse amplitude and skin temperature indicated that local vasodilatation following exposure to noxious stimulation is larger in magnitude and persists longer in the "vulnerable" arm; whereas these reactions are minimized in the arm perceived by the individual to be anesthetic.

The subcutaneous tissue of the forearm was perfused with normal saline and the perfusate analyzed before and after an axon reflex flare was induced by faradic stimulation of the skin (or by intradermal injection of histamine) adjacent to the perfused region (56, 58, 60, 61). With the onset of the axon reflex flare, a substance predictably occurred in the perfusate that relaxed isolated rat duodenum, contracted rat uterus and depressed the arterial blood pressure of the rat. A constant ratio of activity on the several test models indicated that the observed effects of the specimens are due to a single substance. The substance did not occur in perfusates collected during non-neurogenic vasodilatation following ischemia of the arm (reactive hyperemia). The name "neurokinin" has been suggested for the substance thus formed during augmented activity of neurons. A polypeptide with the same properties as the agent observed during axon reflex flare as well as an enzyme capable of forming it when incubated with plasma globulin also have been found in the cerebrospinal fluid of some patients with disorders of the central nervous system. Neurokinin and the relevant protease have also been found in perfusate of the cerebral ventricles of laboratory animals during stimulation of the

brain (70) and in perfusates of peripheral nerve during stimulation (71). In addition to its role in the axon reflex of the skin, neurokinin may serve in local vasomotor control within the central nervous system and may possibly have more direct effects on neuronal function.

Enhanced inflammation has been shown to be effective in combatting invasion by microorganisms and in the rapid elimination of tissue breakdown products of injury. The view is proposed that man includes among his adaptive and protective devices, neural reactions integrated at the highest levels that heighten inflammation in the peripheral tissues and increase the local susceptibility and reaction to injury—thus enhancing the protection of the whole organism at the cost of the integrity of a part. Such reactions at times may be essential to survival. But, if evoked inappropriately or excessively, they can contribute to disease since non-noxious stimulation becomes noxious and mildly damaging stimuli result in greater injury.

In brief, neural activity involving the segmental, brain stem, and cortical levels can modify reaction to noxious stimulation in the peripheral tissues so as to augment or suppress inflammation and tissue damage. A change in attitude towards noxious stimulation may thus increase or decrease inflammatory reactions and tissue damage in part through local alterations in vasomotor function with concomitant increase or decrease of proteolytic enzymes, polypeptides and other humoral substances in the tissue fluid.

THE NATURE OF THE HIGHEST INTEGRATIVE FUNCTIONS OF MAN

Through studies of those with loss of tissue from the cerebral hemispheres it was found that the defects characteristic of conventional concepts of "dementia" or "organic brain damage" (defects in memory, judgment, orientation, simple perception *etc.*) were not predictably present unless the loss was relatively large (more than approximately 120 grams). Indeed, the mean verbal intelligence quotient of those subjects with up to 120 grams tissue loss was not different from that of the general intact population. However, even those

with as little as 30 gram tissue loss predictably demonstrated defects in other aspects of their adaptive capacity. Thus it was found necessary to expand the concept of the functions of the cerebral hemispheres.

Several categories of highest level functions have been defined. First are those functions having to do with the expression of needs, appetites, and drives. Fall-off in these functions is manifest in decreased seeking of challenge and adventure, restriction of imagination, lessened human association and exchange, diminished aspiration and striving, abandonment of previously cherished goals, passive acceptance of circumstances, lessened sexual activity, and when the damage is severe, inadequate response to even the minimal requirements of food, shelter, and warmth.

Second, are those functions having to do with the capacity to respond to symbols as substitutes for biologically significant events, thus employing effectively the mechanisms for goal achievement. These enable the individual to anticipate dangerous or propitious circumstances and to learn, perceive, know, remember, arrange, plan, invent, explore, postpone, modulate and discriminate. Important in this category is the capacity to eliminate responses when they are no longer appropriate.

Third, are those functions that enable man, under circumstances of duress, to integrate elaborate behavior patterns of a defensive or protective nature that are appropriate, adequate, socially acceptable, and sustained.

Fourth, are those functions having to do with the maintenance of organization. These, as mentioned above, serve to lend continuity and maintain stability and proper speed of response and are especially important during periods of stress.

The components of the highest integrative functions are not equally fragile. Impairment of speed of response, spontaneity, imagery, creativity, rapid learning, ease of abandoning a pattern when no longer appropriate, capacity for abstraction, and ability to resist the disorganizing effects of stress are evident in subjects with loss of even small amounts of tissue, whereas vocabulary, long utilized skills, behavior patterns, and premorbidly acquired informa-

tion are not significantly impaired until there is a much greater loss of tissue. With major loss of tissue from the cerebral hemispheres, there is progressive inactivity and finally coma and death.

THE HUMAN BRAIN AND ENVIRONMENTAL INTERACTION

There is much to indicate that the brain itself, in integrating highest level adaptive responses, may be damaged as a consequence of improper interaction between organism and environment.

In men, and in some laboratory animals, the development of brain function may be retarded when in infancy they are deprived of suitable challenge, adequate stimulation, the protection of a parent, and opportunities for successful interaction with the environment. There are instances of infants and children raised in relentlessly hostile environments or in those permitting of no continuing human relationship who have not matured (64). Also, aged persons deteriorate rapidly when they are deprived of their work and social responsibilities.

In man total isolation and severely restricted sensory stimulation are followed by temporary impairment of high level brain functions. Men subjected to the prolonged abuse and hatred of their fellows, as in prison, behave as though their heretofore actively functioning brains were severely damaged. They pass through predictable states of progressive impairment, comparable to the impairment observed in subjects with progressive loss of brain substance. Even when sleep and food are adequate, complete isolation, lack of opportunity to talk, repeated failure, frustration, and reviling by other men can cloud the mind and may make a man confabulate, become more suggestible, and cause him to rationalize behavior previously unacceptable (65).

The quantitative methods developed through the study of individuals with cerebral ablations permitted assessment of highest level brain function in ostensibly intact individuals who had experienced prolonged periods of unresolved difficulties in adaptation. It was found that persons with no evidence of gross anatomic disease of the brain but who, for long periods had achieved no effective adaptation and had

experienced longstanding anxiety and other disturbances in behavior and mood (both with and without bodily disorders), exhibited severe thinking and adaptive difficulties. Indeed, they performed in their usual lives and laboratory test procedures as though moderate and sometimes massive amounts of brain had been damaged or removed. Those with effective defenses such as blaming, rationalizing, sublimation, denying, pretending, or withdrawing from participation, showed less deterioration in brain function. But when these defenses were no longer adequate or stress had been too prolonged, these individuals too, demonstrated a persisting impairment of highest level brain functions.

The observed "mass action" relationship between the highest level functions and the aggregates of neurons in the cerebral hemispheres may give a clue to the nature of the process. For highest level functions the number and degree of arrangement of nerve cells is of central importance, and the pattern of specific localized connections, so important for lower level functions, is of lesser significance. Order itself becomes the relevant attribute for understanding of the relationship between the neuron and the highest level functions.

The property of being highly ordered, is of course, not limited to the brain, but is shared by all living cells. However, the density of arrangement within different bodily tissue varies greatly, reaching its apex in the brain. Thus in our view, although all tissues contribute, by virtue of this high density of arrangement and their great mass, the cerebral hemispheres of man contribute more to highest level functions than do other structures. In a sense, then, "mind" may be said to reside in all cells of the body, a view in keeping with the intuition of the ancients who were reluctant to name the brain or any single organ as the sole residence of mind (69).

The concept that the organization of highly ordered systems featured by purposive, self-regulatory, goal-oriented activities is in keeping with the contemporary orientation of biologists. Sinnott (70) defines mind as "whatever directs the development of an organism toward goals set up

within its living stuff." Accordingly the relationship of the brain to the mind is viewed by us as follows: Mind is the aggregate of purpose and needs, arising from the parts and the whole of the human organism, whereas the brain in addition to contributing to purpose, is the organ of means for maximum adaptive versatility to achieve these ends.

ADAPTIVE REACTIONS AND PSYCHOSIS

These considerations of the consequences of unresolved difficulties in adaptation long maintained, encourage an attempt to reassess the place of psychoses within a general theory of disease. The orientation for this effort is derived from the observation that many hospitalized patients with chronic schizophrenia exhibit a serious impairment of functions of the cerebral hemispheres, an impairment with all of the features found predictably in those with major tissue loss from the isocortex of the cerebral hemispheres, but colored and overlaid with special features that make possible the ready differentiation of schizophrenia in most instances (67, 71, 72).

The nature of the process of schizophrenic deterioration is ill-defined, and indeed, it remains uncertain whether schizophrenia is a single disease entity, even though psychoses of the schizophrenic type occur more commonly in some family stocks.

The evidence previously cited indicates that when an individual perceives himself to be dangerously or overwhelmingly threatened for long periods, and some satisfactory level of overall adaptation cannot be achieved, the functions of the brain are impaired (at first readily reversibly and ultimately less so). Schizophrenic psychoses may be initiated in individuals during such periods. But, in this regard, the schizophrenic reaction differs in no essential way from many other human symptom complexes, and in fact in itself allows of no inferences as to the pathological process involved. As indicated previously, infections, metabolic disorders and behavior changes as well as various enzymatic disturbances may all be initiated in such untoward circumstances.

In addition to the demonstration of serious deterioration of the highest integrative

functions in moderately advanced schizophrenic patients, it has been shown that the cerebrospinal fluid of many schizophrenic patients (73-75) contains unusual amounts of a proteolytic enzyme, unusual proteins, occasionally polypeptides and other products of proteolysis. These substances are also found in the spinal fluid of patients with inflammatory and progressive degenerative diseases of the central nervous system and even after periods of augmented central nervous system activity in otherwise intact persons and laboratory animals (62). The occurrence of increased amounts of these non-specific accompaniments of catabolism in those with schizophrenic reactions suggests that a significant (yet perhaps reversible) alteration in metabolism occurs in the brains of patients so classified. Moreover, the accumulated proteolytic enzyme, other agents, and polypeptides in themselves could contribute to impairment of the functions of the brain.

The data about the abnormality in the spinal fluid bespeak only altered function without defining a category of disease. However, the described change in enzymatic content is compatible with the suggestion that in these patients there is a metabolic disturbance within the central nervous system, either primary or secondary.

A working hypothesis for the mechanism of the impairment in the functions of the cerebral hemispheres of patients with schizophrenia may be suggested. Neuronal excitation and alterations in the patterns of neuronal activity during faulty adaptation, if sustained could lead to persisting disorganization of neural patterns. Since for effective integration the highest level brain functions are dependent upon uninterrupted and proper interaction with the environment and suffer rapidly when this exchange is restricted or distorted, prolonged disorganization of neural patterns would further interfere with proper interaction and perpetuate a cycle that could lead to long-lasting impairment. Secondly, the defensive reactions (denying, blaming, shutting out, *etc.*) result in a reduction of proper interaction of the individual with his environment since they limit, distort, or block perception of the environment or

reduce the participation of the individual.

Further, excessive or prolonged neural activity under such adverse conditions may result in the elaboration of substances originating outside or inside of the brain that interfere with neuronal function. An inborn metabolic defect could contribute to this dysfunction.

DISCUSSION

Since man is a tribal creature with a long developmental period, he depends for his very existence on the aid, support and encouragement of those about him. He lives so much in contact with others and he is so deeply concerned about their expectations of him, that perhaps his greatest threat is their disapproval or rejection. Events having to do with his place in his society take on a major significance and man often functions best when his own ends are totally subordinate to the common end. Inversely, when he is frustrated in such efforts, or rejected by his group, the individual may evoke destructive inappropriate adaptive and defensive reactions or even die. Man is jeopardized not only by those forces that threaten survival of self and kin and opportunities for procreation, but he is also endangered when through the actions of others, his growth, development, and fulfilment of individual proclivities are blocked, and even when his esthetic needs and creative potential are not satisfied.

Challenge is essential and some threat is desirable, if not necessary, for proper human development. But threats to the stability of intimate human relations, especially during the dependent years, and those that wipe out hope and faith in men can have "grave effects."

Many persons have a proclivity for reacting to threat with one particular adaptive pattern, for example, one involving the stomach, rather than the large bowel; or with blaming rather than compulsive activity. They may react to threats in this way for many years, using other patterns only now and then: once established many patterns appear to be self-perpetuating. Several members of one family often show similar patterns. However, even though a given person when confronted by a similar situation usually reacts in the same way, when a new significance is attached to the

situation, new adaptive patterns may appear. In the course of a lifetime several different patterns may be established in those who are threatened by numerous circumstances or who only transiently achieve a suitable adaptation.

Man's special capacity to react to *symbols* as though to significant *events*, enhances his ability to perceive threats as well as to increase his satisfactions. How, then, he perceives his immediate environment depends on his inborn equipment and early conditioning as well as on a host of life experiences. Since pain or damage to tissue provokes vigorous general and local protective reactions, symbols of destructive experience can also evoke such reactions, often to a degree far more costly to the individual than the actual effects of the assaults they symbolize. Moreover, aspiration, creativity, abhorrence of boredom and need of change are central aspects of human activity. At times of his greatest vigor, man is ready to abandon the safe, the certain, the predictable and the secure for challenge, increased responsibility, uncertainty, adventure and exploration. The utopias, the idyllic pastoral tranquility he dreams and talks about, he forgoes to fulfil his humanity. In so doing he may seriously jeopardize the adaptative arrangement most compatible with health. Illnesses of all kinds—impairment in function, reversible or otherwise, with and without obvious tissue damage—are aspects of attempts at adaptation during striving to attain human goals.

PSYCHIATRY, NATURE AND SCIENCE

MARTIN HOFFMAN, M.D.¹

MAD, adj. Affected with a high degree of intellectual independence; not conforming to standards of thought, speech and action derived by the conformants from study of themselves; at odds with the majority; in short, unusual.

Ambrose Bierce(2)

In his discussion of psychiatry and the law, Thomas Szasz made a remark which bears an unusual resemblance to the apparently merely cynical and witty one quoted above. He states:

Whenever we try to give a definition of what mental health is, we simply state our preference for a certain type of cultural, social, and ethical order(14).

If this be so, there really is no such thing as a scientific definition of mental health or illness. That such a point of view would lead to many significant changes in both psychiatric theory and practice goes without saying. It seems, therefore, to warrant careful inquiry. Although psychiatrists, being practical men, do not usually welcome philosophic analysis into their professional province, there are times when such inquiry is absolutely necessary to clarify ideas in daily, "practical" use.

I propose, therefore, to explore the philosophic and scientific origins of this viewpoint in order to clarify what seems to be one of the crucial issues of modern psychiatry. Naturally, an exhaustive treatment of this question would fill a volume. However, by a brief survey of the problem, with references to the pertinent literature, some very significant conclusions should emerge. I shall discuss first the classical doctrine of Natural Law, then the viewpoint of modern science on values, and finally the concept of "health" in psychiatry. A few remarks on applied psychiatry will close the paper.

I. THE THEORY OF NATURAL LAW

The idea of Natural Law is stated by Professor John Wild as follows:

By natural law or moral law I mean a univer-

sal pattern of action applicable to all men everywhere, required by human nature itself for its completion(17).

As is obvious from this quotation, the doctrine of Natural Law is based on the doctrine of "human nature." It implies that there is an ideal standard for "all men everywhere" which is attained when our "human nature" is completely realized or fulfilled. Now, while we speak of "human nature" today, we usually do not mean what the originators of the Natural Law doctrine, Plato and Aristotle, meant by it.

The classical conception of "human nature" was based on the idea of "nature," which may be stated as follows: there is in living beings (and in certain other elements of the universe, also) an *active tendency* working toward the realization of the form, essence, or nature of the being in question(1). The essence or nature was determined by the particular species to which the individual being belonged; in fact, this essence or nature *defined* the species(5).

For example, there was in an acorn the active tendency to develop into the end for which the acorn was designed, *i.e.*, an oak. All animals had as their "purpose" the realization of their particular natures, *e.g.*, "dogness," "catness." Man was a more complex being than the other animals, but he too had a nature, which was realizable by a combination of forces. The equation by Professor Wild, of Natural Law with "moral law" indicates that at least one of these forces was the individual's ability to make choices. Other forces included hereditary factors, social class, education, *etc.* But there was for man an ideal which could at least be approximated by some fortunate individuals.

Now, in connection with this doctrine of Natural Law, at least two things need to be said. First, modern science has abandoned it. This abandonment is based on the rejection of "nature," which may be dated in physical science from the time of Copernicus and his successors(12), and in biology

¹ From the Department of Psychiatry, State University of New York, Upstate Medical Center, Syracuse, N. Y.

from the time of Darwin(5). Our view of the physical and biological universe is no longer teleological.² Science may describe *how* an acorn becomes an oak, but it does not postulate any "purposive regulative principle," to use Dewey's term(5), in the acorn actively directing it towards its goal. The concepts "end," "purpose," "nature," "essence," *etc.*, are no longer accepted scientific terms. Science, which in general works according to the principle of not multiplying entities without necessity ("Ockham's Razor"), is able to explain the data presented to it without these concepts. Consequently the idea of a "human nature" and of a Natural Law have been abandoned.³

The second point with regard to this rejected doctrine of Natural Law and of the doctrine of "human nature" is, that these concepts are still to be found in daily scientific (including medical and psychiatric) discourse. It is a purpose of this paper to investigate the derivatives of the theory of Natural Law which are present in current psychiatric terminology and preceding this, to discuss the current place of values in scientific theory.

II. THE DOCTRINE OF SCIENTIFIC VALUE RELATIVISM

The problem of values has of late become the crucial issue in modern social science. This is especially so in political science as it is this branch of knowledge which deals with the formation of policy. The origin and scope of this problem in its relation to political science have recently been the subject of a book, *Political Theory*, by the distinguished scholar, Arnold Brecht (3). Brecht comes to the conclusion that scientific method is the only source of knowledge that can be called "intersubjectively transmissible," *i.e.*, that rests on legitimately communicable evidence(3). He feels that acceptance of scientific method as our sole source of transmissible knowledge implies the acceptance of what he calls "Scientific Value Relativism."

By Scientific Value Relativism, which Brecht calls the "seamy side of Scientific Method," he means: "the validity of the ultimate standards that underline value judgments cannot be established through Scientific Method." This is due not only to the abandonment of the theory of Natural Law, but also to the realization of the "Logical Gulf between Is and Ought":

Deductive analytic logic . . . can add nothing to the meaning of propositions; it can merely make explicit what is implied in that meaning. Inferences of what "ought" to be, therefore, can never be derived deductively (analytically) from premises whose meaning is limited to what "is."

In short, science cannot set goals, cannot tell us what is "good" or what is "bad."

That this doctrine has evoked a storm of controversy may well be imagined.⁴ However, none of the objections, which are dealt with at length by Brecht, can overcome the threefold argument that: 1. Scientific method is the only method which yields transmissible evidence for hypotheses; 2. The doctrine of Natural Law and the idea of nature on which it is based have been abandoned by modern science as not verifiable; and 3. There is no way to bridge the logical gulf between statements of fact and statements of value.

As a result of this admittedly brief examination of the views held by the great majority of contemporary philosophers of science we have reached a conclusion of immense significance: science cannot establish a hierarchy of values. It can, of course, deal with values as *means*, but never as ends. While it may state, for example, that it is "good" to have a certain sort of police system if the greatest amount of individual freedom is the end, it can never say that individual freedom is the highest good or that it ranks high in the "real" value hierarchy.

What this means, further, is that in its inability to set ultimate values, science can-

² For a valuable discussion of the current status of teleology and the concept of "function" in biology, see Nagel(10).

³ On the various concepts of "law and nature," see Whitehead(16).

⁴ For a remarkably subtle and perceptive statement of the grave implications of Scientific Value Relativism, see the writings of Leo Strauss, particularly the Introduction to *Natural Right and History*(12), and the series of collected essays, *What is Political Philosophy? and Other Studies*(13).

not rationally define "the good," i.e., it cannot say what "the good" is. In analogous manner it cannot define such a term as "justice," for "justice" also requires for its proper definition the setting of an ultimate value hierarchy. In the following section we shall examine yet another value term with the foregoing ideas in mind.

III. THE ATTEMPT TO DEFINE "HEALTH" IN PSYCHIATRY

For many years, workers in the field of psychiatry have been concerned with the fact that no really acceptable scientific definition of "mental health" (or "mental illness") exists. Recently, two very able summaries of the literature dealing with this problem have appeared. One is by the social psychologist, Marie Jahoda(7), the other is by the psychiatrist, Frederick Redlich(11). I shall not attempt to summarize the summaries, but shall only remark on their statements about values and on their conclusions.

Jahoda concludes that, "By far the most urgent need in the field is for more knowledge." She does not actually offer a definition of mental health. Her main emphasis seems to be that mental health is more than the absence of mental illness; hence the phrase "positive mental health" in the title of her book. Jahoda's presentation is followed by a statement by Dr. Walter E. Barton, who speaks as a clinician and more-or-less *does* prefer to think of mental health as the opposite of mental illness. As will presently be apparent from the argument of this paper, this issue is not a scientifically legitimate one.

More interesting to our discussion is Jahoda's statement on values:

Actually, the discussion of the psychological meaning of the various criteria [for positive mental health] could proceed without concern for value premises. Only as one calls these psychological phenomena "mental health" does the problem of values arise in full force. By this label, one asserts that these psychological attributes are "good"(7).

In Redlich's paper on the concept of health in psychiatry, he states:

Most propositions about normal and abnormal behavior contain normative elements. We con-

cur with Reider that the question as to normal or abnormal usually turns out to be a question about good or bad(11).

As we have seen above, any statement of what is good or bad is beyond the legitimate range of science, as it always involves a reference to ultimate standards of value. Redlich concludes his excellent discussion of varying conceptions of "mental health" with the following remarks:

We do not possess any general definition of normality and mental health from either a statistical or a clinical viewpoint. In any case, meaningful propositions on normality can be best made within a specific cultural context.

In other words, our attempt to define "health" in psychiatry has not really produced satisfactory results, and we always have to define "health" within a specific cultural context of values. It would seem that our difficulty in defining "mental health" is due *precisely* to the fact that it is not properly a scientific term. In fact, it can only be meaningful when ultimate values have already been postulated by some extra-scientific (e.g., religious, cultural) means. It may be doubted whether any two theorists in the field will ever agree on the same order of ultimate values. Consequently we shall never have a "true" definition of "health" within legitimate scientific discourse, any more than we can have a scientific definition of "justice."

Even the venerable psychiatric terms "neurosis" and "psychosis" are subject to scientific objection on grounds analogous to the objection to the term "health." This is when they are used—as they most often are—simply and loosely as value terms, without reference to a definite scientific hypothesis, such as Kubie's on "neurosis"(8).⁵

For an extremely cogent discussion of many of the issues presented in this paper, from a somewhat different perspective, see the article by Hollender and Szasz appropriately entitled, "Normality, Neurosis and Psychosis"(6).

One might well inquire why it is so easy to work with the concept "physical illness" as contrasted with "mental illness." This is

⁵ Kubie's formulation implies a value judgment as presently stated(8); to that extent it is outside science. But it also contains a genuine scientific hypothesis, which is theoretically capable of being stated in terms that would allow it to be tested experimentally.

the case, I submit, mainly because almost all people in our culture agree about the values associated with bodily function. Absence of pain and other bodily discomfort, plus certain regularities of function, (e.g., food intake, excretion, sleep) are virtually universally accepted values.

But strictly speaking, organic medicine really faces the same problem as psychiatry, i.e., its definition of "health" is essentially not arrived at by scientific inquiry but rather by social agreement. In biology, no less than in psychology, science cannot set goals. The philosopher Morris R. Cohen writes :

We are thus constantly passing value judgments (in terms of final causes) when we speak of things as normal or abnormal, the average man, and especially when we use the term "pathologic." In biology, there is no difference between normal physiology and pathology, except in our point of view as to what we consider the end of the process(4).⁶

Whether or in what fashion a particular case is designated as "disease" depends to at least a major extent on the way it combines two variables : 1. Its ability to cause suffering and/or death ; and 2. Whether or not it brings the individual into conflict with society.

The reason why the definition of organic illness has almost always been (erroneously) viewed as a product of "nature" rather than of "convention" and has thereby had its true character obscured, is that in virtually all cases both society and the patient agree on what constitutes undesirable phenomena, i.e., "illness." This is true, of course, for a considerable portion of psychiatric phenomena as well, e.g., depressions, ob-

sessional states, schizophrenic panic. These states may be characterized by the fact that they cause psychological suffering yet do not bring the patient into any substantial conflict with society. Persons other than the patient agree as to the undesirability of these states because they are able to identify with him. This is true of organic illnesses also.

A second class of phenomena neither cause suffering nor bring the individual into any substantial conflict with society. There is no agreement at all about the labelling of these "borderline" conditions as "disease." Examples are the business man "driven" to success who does not feel "ill," the pacifist, the religious martyr. These are usually labelled as "psychopathology" by theorists who have different standards of value from the individual in question. Along with this group of phenomena one may consider those discussions pertaining to society in general, such as the arresting statement of Kubie's that the neurotic process is pervasive in our entire culture(5). While all these questions are very interesting and, in fact, quite important if properly considered, they can well become the focus for a host of pseudo-problems if considered as questions of "psychopathology" without reference to the issue of ultimate values.

There exists yet a third class of psychiatric phenomena, which society designates as "disease" but in which the patient is not convinced. Examples are paranoid schizophrenia, mania, and some of the sexual "perversions." These conditions in themselves cause no suffering to the individual but bring him into grave conflict with society. (This conflict often does, of course, lead to "secondary" distress.) Persons other than the patient are unable to identify with him because the individual here is engaged in activities (e.g., unusual types of thought process, deviations from the sexual norm) which are perhaps of all human behavior the most subject to social condemnation.⁷

⁶ One can make a valid distinction between organic and psychological medicine as Szasz does in his paper, "Language and Pain"(15). This distinction highlights the philosophic issue of values discussed here. It does so because of the widespread lack of agreement about values in the psycho-social or behavioral area as contrasted with the quite general agreement about values in the organic or physiological area.

The argument of this paper is, however, by no means dependent on such a distinction, for the inability of science to set goals cuts across all dividing lines—however correct they may be—between its various branches. Therefore, even one who rejects dynamic psychology and believes that all "mental illness" is due to chemical factors can still accept the thesis of this paper.

⁷ It is an interesting scientific question just to what extent the very existence of society is dependent on the repression by the majority of persons of tendencies to these particular forms of "abnormal" behavior. It may be added parenthetically that the solution of such a question—like that of any genuinely scientific question—does not require that the investigator make value judgments on the phenomena under scrutiny.

Besides these three groups there also exists what might be called a subclass of psychiatric phenomena which "completes" the possibilities inherent in the "two-variable" system of classification I have used. Here the individual is in distress and is also in conflict with society. I say "subclass" here because usually there is an inverse relation between the distress and the conflict; the patient "acts out" in order to avoid or diminish distress. Thus either distress or conflict predominates and the patient falls into one of the other groups.

In cases where both society and the individual agree, there is no practical problem about the acceptance of the label "sick." Here the psychiatrist has as his job the alleviation of suffering. Should a psychiatrist be consulted where there is a conflict between the patient and society he must decide if he can resolve the problem to the mutual satisfaction of both. If he cannot, he must then decide whom he will serve. Finally, there are the "borderline" cases, such as religious martyrdom, where there is no substantial agreement at all. Such cases do not come to the psychiatrist by way of the consulting room, but rather are of interest to him insofar as he is a scientific student of human behavior.

Psychiatry can study any of the above issues scientifically, provided this is done in a "value-free" context. This does not mean that we blind ourselves to the fact that society deals with these issues in a web of values. It means that we do not *qua* scientists make value judgments which are dependent on a hierarchy of ultimate values. Both Redlich and Jahoda stress the need for more research. In that we are all in agreement. But to expect a scientific definition of mental health as an outcome of such research is to expect the logically impossible.

IV. ON "APPLIED PSYCHIATRY"

The value judgments which are forbidden to enter through the front door of political science, sociology or economics, enter these disciplines through the back door; they come from that annex of present day social science which is called psychopathology.

Leo Strauss (13)

In his paper on psychiatry and the law referred to above, Szasz takes essentially the

same position with regard to the concept of "mental health" as is found here (14). It is important to note why this position is of special relevance in this context. This is so precisely because the influence of psychiatry on law is one of those "borderline cases," referred to earlier, where general agreement about "mental health" does not exist.

The neglect of this consideration has led to a great amount of confused thinking, and to an even greater amount of confused writing, about "advances" in the area of "applied psychiatry." Careful reflection would, of course, show that the very existence of a criminal act on the part of any individual could, under someone's definition of mental illness, be enough criterion to diagnose him as sick. Therefore *all* criminal acts would really be *symptoms* of "illness"; criminal jurisprudence would emerge as a subspecialty of medicine, and (to carry the argument to its logical conclusion) criminal lawyers, judges, and law enforcement officers would be required to go to medical school as part of their training.

If this example appears absurd to the reader, let him reflect that it is simply an extreme expression of what might happen in applied psychiatry if psychiatric "knowledge" is applied without regard for the fact that social consensus is the only way to define mental illness. The confusion in the area of criminal law arises because it is not recognized that the labelling of some acts as due to "illness" and some as due to "badness" is nothing but a purely social or conventional process. The problem is actually one of how to deal with people who commit anti-social acts. Society must solve the problem itself on the basis of its own goals and on the basis of its own judgment as to the best means to these goals. While science may be of aid in the problem of means, it cannot prescribe the ends or goals.

CONCLUSION

It is a purpose of philosophic analysis to clarify the meaning of concepts used in scientific discourse. An attempt to do so has been made here, with special reference to the value-terms used in psychiatry. Such terms as "mental health," "mental illness," "normal," "abnormal," "neurosis," "psy-

chosis," "perversion," "psychopathic" or "sociopathic" personality have been subject to scrutiny. It has been shown that such terms cannot be defined scientifically. Therefore, it is suggested either that they not be used or that a precise statement of the basis of their use in any given case be made. Such attention to our use of language will bring rewards both in the clarity of our discourse and in the elimination of issues hitherto considered unsolved problems of science.

PSYCHIC INGREDIENTS OF VARIOUS PERSONALITY TYPES

MARTIN B. GIFFEN, M.D., JAMES A. KENNY, M.S.W., AND
THEODORE C. KAHN, Ph.D.¹

The "soft underbelly" of psychiatry is its nomenclature. We may know dynamic theory and be effective psychotherapists. But when confronted with the task of expressing our diagnostic impression in clear, short, and precise terms, we sometimes encounter a frustrating semantic block. Either we are not certain a particular psychiatric label accurately describes the condition; or we are subjectively convinced that a certain diagnostic label is appropriate, but have difficulty explaining why.

We need not go into the question of whether the present diagnostic terms should be supplanted by new ones. This time-worn subject has already had its share of argument(1). Instead, we wish to attempt a new approach to the subject: what actual ingredients are to be found in personality types characterized by the clinical labels used in psychiatry? To answer this question we propose to use a relatively new psychological test described in this journal several years ago(2): the Kahn Test of Symbol Arrangement.

This test represents a radical departure from other psychological techniques in that it embodies the concepts of the newer *existence psychiatry*. Instead of exploring projections, it explores the way a person arranges and deals with common symbols of everyday life. Kahn recently pointed this out in a workshop on this test held at the Mount Sinai Hospital in New York(3). One of the many new aspects of the test is that it yields a symbol pattern for each test subject that is characteristic of him and no one else. The symbol patterns, however, fall into well-defined areas corresponding to clinical entities recognized by psychiatry(4). The validity of the instrument in classifying patients into correct diagnostic groups has been demonstrated often(5, 6, 7, 8, 9, 10).

In order to accomplish our purpose it is necessary to reverse the usual procedure of

validating psychological tests. Rather than matching test results with psychiatric diagnoses, we shall attempt to explore the major diagnostic categories by an analysis of the symbol patterns of the Kahn Test. In doing this we must be aware of the possibility that we may be following our own tail. It could be argued that the Kahn Test was first validated on psychiatric opinion from which the symbol patterns were built up. If we now attempt to explain psychiatric nosology by these same patterns, it would seem that we are merely returning to our starting point. This, however, is not so. First of all, the development of the symbol patterns included more than a mechanical matching of patterns with psychiatrically defined traits. Secondly, much of the development of the test centered around capacity to identify membership in a clinical group by means of the symbol pattern alone (11). Mills points out that this is possible because the test uses "the language of sociological entities"(12, 13). Murphy, Bolinger, and Ferriman(9) state:

Finally, by providing definite formulas which are applicable to specific nosological groups, the psychologist has, at last, his chance to attempt to be scientific. . . . The danger of projecting oneself into the test situation, and factors such as the "halo effect" and countertransference are, thus, minimized.

We must first understand that the Kahn Test is scored on 9 apperceptive-abstractive levels. The patient responds to 16 colored or transparent, plastic symbols used on the test. These consist of objects shaped to resemble butterflies, hearts, dogs, stars, a cross, a circle, an anchor, and a parrot. In stating what these objects can represent, the patient's solution can fall into any of the following categories:

- A—Bizarre, autistic (as defined in the test manual) (14).
- B—No symbolization (patient unable or unwilling to comply).
- C—Repeat of previous response (patient states: "same as before").

¹ Dr. Giffen is Consultant in Psychiatry, Surgeon, United States Air Forces, Europe. Lt. Kenny is Chief Psychiatric Social Worker, and Dr. Kahn is Chief Psychologist, USAF Hospital, Wiesbaden, Germany.

- D—Naming what the object is instead of symbolizing.
- E—Associations by shape or form of the objects.
- F—Associations based on color of the objects.
- X—The thing with which the patient associates the test object has the same shape as the test object itself (example: "An anchor represents an anchor on a ship").
- Y—The association represents something with a different shape from the test object; however, the association is tangible (example: "An anchor stands for the ocean, the navy, a sailor").
- Z—The association represents something that is not tangible and also differs in form from the test object (example: "An anchor stands for transportation, travel, adventure, or restlessness").

Each of the above responses is given a numerical weight. This weight corresponds to the statistical deviation of the response in terms of frequency of use from a carefully-screened, normal, control group (11, 15). The use of 500 normal subjects in the formulation of the Kahn Test scores represents a meaningful departure from validity attempts in which only clinical groups are used. Additionally, over 2,000 normal subjects were used in the test's standardization (11, 16).

In addition to the numerical score, the letters designating the category of responses are arranged in order of frequency to form a letter (frequency) element. The combination of the numerical weight with the letter element is called the *symbol pattern*. For a normal individual a typical pattern is: 100-ZYXEFD. This means that numerical score of 100 represents minimal deviation from normalcy. More Z responses than any other type of responses were given; Y responses were next in terms of frequency. The frequency then decreased in the order XEFD with B responses in the minority.

An analysis of the cognitive-behavioral factors associated with the letters was made by Kahn (17). These are briefly summarized as follows:

- A—Divergent from norms as defined by test manual; autistic; deviant in thought processes.
- B—Lacking cognition with no attempt to perform; resistant; evasive; fearful of self.
- C—Rigid; compulsive; unimaginative.

- D—Lacking cognition with attempt to perform; inhibited; emotional blocking.
- E—Apperceptively aware; materialistic.
- F—Artistic; labile; manic.
- X—Form bound; lacking in capacity to emancipate oneself from stimulus; limited powers of abstraction.
- Y—Discerning of reality with only partial emancipation from stimulus.
- Z—Creatively imaginative; idealistic; capable of abstraction in dealing with cultural media.

Using the above characteristics, we shall examine how they apply in exploring the psychic ingredients of the clinical groups tested by the numerous researchers with the Kahn method (5, 6, 7, 8, 9, 10, 11). This method will furnish a basis for understanding the nature of these clinical groups never previously afforded us. Kahn has found the following *symbol patterns* typical:

VERY SUPERIOR NORMAL²

125+; Z is first letter in pattern; YX or XY follow Z.

Discussion: The numerical element of the *symbol pattern* seems to be correlated with the I.Q. among normal children (18) as well as among normal adults (1, 18). From the letter element of the *symbol pattern* we find that active imagination and idealism predominate in the psychic make-up. Rigidity (C) and Inhibition (D) do not take precedence over Reality Discernment (Y) and Form Adherence (X).

NEUROSIS

71-89; either Y precedes X and Z or B, C, or D appear in the first two letters.

Discussion: First, we note the lowering of the numerical element indicating loss in overall efficiency. (The approximate percentage of loss can be estimated by comparison with the obtained I. Q.) Z responses no longer dominate. The relatively greater frequency of Y responses signifies a "return to the stimulus," a lack of emancipation. Loss of active imagination and idealism are indicated. Kahn points out (11) that in some types of neuroses, B dominates, indicating anxiety or depression. In these cases "fear

²Typical *symbol patterns* cited in this paper are all taken from Clinical Manual, Kahn Test of Symbol Arrangement, pp. 154-5(11).

of self" is dynamically significant. Among hysterical neuroses, D is usually prominent as symptomatic of inhibition and emotional blocking. Obsessive compulsives may have a number element much higher than other neurotics indicating an intactness of intellectualizing processes. However, as Kahn points out, in practically all cases C is found among the first two letters showing the compulsive to be rigid, inflexible, and unimaginative.

CHARACTER AND BEHAVIOR DISORDER

51-70; X precedes C and Y; C prominent; Z weak or absent.

Discussion: The authors have often pondered over the paradox that the characterological patients (the "psychopaths" or "sociopaths") are held legally most responsible for their actions. Yet they are probably the only ones who are morally innocent. This represents one of the frustrations of legal-medical psychiatry. Perhaps it can be explained in terms of the law's unexpressed desire to protect society from these people. Virtually, by definition, the characterologically defective individual, having a defective superego structure, fails to comprehend moral implications of antisocial acts. He lacks the mechanism for this comprehension except on an abstract, intellectualized level. He views the world as a place where everyone "takes advantage." He then retaliates in conformity with his own warped norm of antisocial behavior.

As one would expect, symbol functioning is significantly lowered under such conditions. The predominance of X responses shows the characterological patient to be incapable of emancipation from the immediate stimuli about him. He suffers from a "fixed focus" so to speak (high C), and is as rigid and compulsive as the obsessive compulsive neurotic. He lacks, however, the neurotic's high Y, and has a significantly lower overall numerical element in his *symbol pattern*. This indicates a far lesser capacity than the neurotic to communicate in the "language of sociological entities" (12).

It is of great interest to note that the typical *symbol pattern* of persons with characterological orientations corresponds to that which is found among average pre-adolescents (11). The total number of letters

in the pattern roughly corresponds to the patient's capacity to utilize various ego-defense mechanisms. Thus it is not surprising that Kahn has found 5 or fewer letters in the pattern to be typical of aggressive and assaultive personalities among characterological persons.

SCHIZOPHRENIA

40-50; either A appears in the first two letters or B, D, and X are spread so that they do not all appear in the first 5 letters.

Discussion: This is only one of several formulas Kahn offers (11) for schizophrenia. He has found that any score below 50 indicates psychosis. The only possible exception to this would be malingerers. The psychotic appears to lack capacity for symbolic functioning along the lines demanded by his cultural environment. The presence of A shows that he has substituted autistic meaning for social meaning. The implication is that he, having withdrawn within himself, is now communicating with himself in a secret language. He is distinguished from the patient with organic brain disease by one of two indices: either the relatively higher A content or the lack of B combined with the use of D and X. In other words, either the subject is autistic, or he attempts to comply but lacks cognition and exhibits limited powers of abstraction. The schizophrenic appears more versatile than the brain-damaged patients. This versatility is reflected in the greater spread of B, D, and X responses so that they are not all found among the first five letters. The relative versatility in the use of ineffectual ego-defenses appears to distinguish the schizophrenic from other psychotic entities in the 40-50 numerical score range.

PSYCHOSIS WITH BRAIN DAMAGE

0-39; B, D, and X all appear in the first 4 letters.

Discussion: The ravages of this disease group are well illustrated by the low numerical element. The emptiness of this illness complex is illustrated by the automatism of naming the object (D responses) instead of symbolizing or abstracting. Lack of capacity to abstract is manifested also by not attempting to perform (B responses). The highest abstractive capacity

present is X, which is a form-bound approach to the stimuli presented in the test.

It is interesting to note the progression of the organic deterioration as reflected on the Kahn Test. Organics with relatively little impairment have a high C (rigidity) component, as well as other signs not expressed in the *symbol pattern* but evident in the clinical evaluation of the total test protocol (11).

SUMMARY

The usual method of validating psychological tests by comparing them with clinically-defined psychiatric categories has been reversed. Instead, various personality types bearing psychiatric labels have been assessed by means of *symbol patterns*. A few examples have been given to illustrate the method. Superior normals are found to excel in creative imagination. Neurotics appear to be only partially emancipated from the stimuli of objects. Persons with characterological personalities appear to have been fixated at a pre-adolescent level of symbol perception. Schizophrenics use symbols autistically. And deteriorated organic patients show a lack of capacity to deal symbolically with their environment except on a concrete and unimaginative level.

These findings are not new and are readily accepted by persons familiar with mental patients. Yet it is interesting that we were able to distinguish the different psychiatric categories by means of *symbol patterns* found typical of the various disease groups.

FURTHER STUDIES OF THE DOCTOR AS A CRUCIAL VARIABLE IN THE OUTCOME OF TREATMENT WITH SCHIZOPHRENIC PATIENTS

JOHN C. WHITEHORN, M.D., AND BARBARA J. BETZ, M.D.¹

For a number of years now, we have been carrying out a series of studies designed to establish definite reliability *what makes a difference in determining improvement* in the treatment of schizophrenic patients. These studies have focused on the nature of the transactions between schizophrenic patients and their physicians. More specifically in recent studies, the focus has been on the contrasting personal characteristics of those physicians who have a high proportion of their schizophrenic patients improve, as contrasted with those who have a relatively lower proportion improve.

That certain physicians engage more effectively as therapeutic partners with schizophrenic patients than do certain other physicians was demonstrated in earlier studies (1, 2, 3). This difference in effectiveness is large. In an initial study, 7 psychiatrists who had averaged an improvement rate of 75% in their 48 schizophrenic patients were contrasted with 7 who had a 27% improvement rate in 52 such patients.² For

convenience, the groups were labeled A and B. Both physician groups did equally well with other types of patients; and schizophrenic patients treated by both groups were initially clinically comparable.

A study of the clinical records of these 100 patients showed that trustful communication was highly associated with improvement, and occurred with greater frequency in the experience of the A than of B doctors. It was also found that B doctors tended to be passively permissive or to point out to a patient his mistakes and misunderstandings and to interpret his behavior in an instructional style. The A physicians did little of this, but expressed personal attitudes more freely on problems being talked about, and set limits on the kind and degree of obnoxious behavior. The patients of A physicians were also those who reached the highest levels of excellence of improvement.

It was also found that when the patient's behavior is grasped in terms of meanings and motivations, it becomes intelligible to his physician (and often to him) in terms of human issues and problems of social interaction. This shared intelligibility seems to reduce the patient's alienation, with improved capacity for social self-assertion and an attenuation of clinical "schizophrenia." For example, the apparent lack of accommodation to the social milieu becomes intelligible—more frequently to the A than the B physician—not as just a lack, but as a positive social action expressing hateful and fearful distrust of himself and others. These feelings of pervasive distrust operate to hamper the actualization and use of real inner potentialities for social strength. The development of capabilities for more confident interaction is a major gain when the outcome of treatment is favorable.

¹ From the Henry Phipps Psychiatric Clinic of the Johns Hopkins Hospital. This work has been supported in part by funds from the Scottish Rite Committee on Research in Dementia Praecox of the Supreme Council, Thirty-Third Degree Masons, Northern Jurisdiction, administered by the National Association for Mental Health.

² The appraisal of the patient's condition at discharge is made not only by the physician who treated the patient, but also by the senior resident psychiatrist and by the psychiatrist-in-chief (J. C. W.). Any personal bias of the individual physician is thus, presumably, subject to correction by the clinical judgment of more objective observers. For purposes of a scientific inquiry where the clinical progress of patients is itself used as a major criterion for evaluating psychotherapeutic processes, objective evidence supporting the validity of the appraisal of the patient's progress is desirable. Evidence was sought from the following 4 sources: 1. The disposition of the patient at the time of discharge—whether to community or to another hospital; 2. Evidence of increased participation in social relationships with other patients, as recorded in the nurses' daily notes; 3. Increased participation in the clinic activity programs, as recorded in nursing and occupational therapy reports; and 4. Changes in Behavior Chart markings. The num-

ber of markings in each of the 4 behavior zones during the first 10 days after admission and the last 10 days before discharge were counted and the direction of shift noted. These data supported the clinical appraisals of the patient's progress.

These findings were cross-validated on another set of 18 physicians and their 109 schizophrenic patients.

In a follow-up study on these two sets of patients 5 or more years after discharge, 70% were rated as still improved.

The findings in these studies indicate that schizophrenic patients (70% as a minimum estimate) have latent potentials for becoming personally and socially more effective human beings, and for sustaining this improved status.

A favorable turn in the clinical course is not readily achieved with schizophrenic patients. Our studies show that some physicians seem able to do so more readily than others. In what perspective can a valid understanding of this difference in effectiveness be sought? Is it an expression of differences in the physicians' personalities? Are personal qualities significant, perhaps even crucial, variables in determining the outcome of treatment with schizophrenic patients? Can contrasting personal qualities distinguishing A from B physicians be demonstrated and characterized? And can the relevance of such differences to the outcome of treatment be discerned?

A series of studies has been carried out, designed to explore answers to these questions. Specifically, we have been focusing on the interest patterns of A and B physicians as revealed by the Strong Vocational Interest Inventory. This approach has provided a successful, independent method for discriminating between A and B physicians. Some of the findings from these studies will now be presented.

The Strong Inventory appealed to us as a research tool because it is well standardized and because it is not primarily psychopathologically-oriented but focuses on human interests. It is a test which selects from a fairly wide range those interests which are highly shared by an individual with some groups of his fellow beings, and those interests only slightly shared with other groups. In all, the Inventory matches the interest patterns of any given individual with known interest patterns of individuals in 45 vocations, by a scoring scale ranging from high to low matching. (All tests in these series were machine scored by the Testscor Service in Minneapolis.)

FINDINGS

For the present report, the research material consists of 50 physicians whose therapeutic results with schizophrenic patients is known, and on whom Strong Vocational Interest Test scores were obtained while they were in residency training. Twenty-six of these physicians constitute the first 2 series of physicians (all but 3 who did not take the test) on whom our original studies of styles of clinical transactions with schizophrenic patients were based (15 A and 11 B).³ The remaining 24 physicians represent a separate group accumulated subsequently, on whom Strong Test scores are available and whose therapeutic performance with their schizophrenic patients during their residency training became known.

As an initial step in analyzing this material, a comparison was made of the Strong Test scores of the 15 A and 11 B physicians on whom our earlier clinical studies had been based. From this comparison some interesting findings emerged. There were 3 vocations in which both physician groups scored high: Physician, Psychologist and Public Administrator. In 10 vocations, both groups scored low (Veterinarian, Mortician, Banker and Policeman among others). In 23 vocations the scores in both groups ranged in a random way from high to low (Musician, Minister, President of a Manufacturing Concern, for instance). And in 4 vocations, the B physicians tended to score high somewhat more frequently than the A physicians, but the percentage differences were not great. (Osteopath, Carpenter, Industrial Arts Teacher and Vocational Agricultural Teacher.)

By the scores on 4 vocations, however; it was possible to detect definite differences in the interest patterns of the A and B physicians. These 4 vocations are lawyer and C.P.A. (A's high B's low); Printer and Mathematics Physical Science Teacher (A's low B's high). The actual findings are shown in Table 1. (The differences are at levels of statistical significance between .10 and .02 by the Chi Square Test.)

These empirical findings—the high fre-

³ An improvement rate of 68% or more is used as the criterion for this discrimination throughout these studies.

B Physicians	11	2	18%	1	9%	6	54%	8	73%

quency of interest patterns for Lawyer and C.P.A. and the low frequency of interest patterns for Printer and Mathematics Physical Science Teacher, which distinguish the A physicians from the B physicians—are independent data constituting a source of possible clues to some distinguishing personal characteristics of each physician group relevant to their different therapeutic results and their different styles of clinical transaction with schizophrenic patients.

DEVELOPMENT OF FIRST PREDICTIVE SCREEN

At various stages in our study we considered in detail how these observations on interest patterns might serve as a predictive device to indicate which physicians would have high improvement rates with schizophrenic patients and which would not.

We had no particular interest in any direct application of such a predictive device in the assignment of physicians to patients. In fact, we wished to avoid any such manoeuvre, intentional or unintentional, because it could bias our investigation. Nor were we concerned to supply others with a practical aid in assigning physicians to patients. Rather we thought that a predictive study, if successful, would serve as a rigorous check on the validity of the differences observed in the first study.

Furthermore, the level of predictive accuracy might serve as an indicator whether the crucial determinants of successful interaction lay in the doctor or in the patient. We have been keeping in mind the possibility that the A doctors might have owed their A rating to the good luck of getting schizophrenic patients who, for some reason, unknown to us, had the knack of establishing confidential relationships, etc.

Such an hypothesis had not seemed to us probable, but it did seem possible. If, however, success in therapy with schizophrenic patients could be predicted in advance, with reasonably high reliability, from indicators of the physicians' characteristics, such a result would support the idea that the crucial determinants of success lay in the physicians.

At one time we tried combining 8 selected vocational scores. We have also tried screening devices based on combinations of 3 or 4 and 5 scores. We have finally developed a 5-point screening device embodying the 4 vocational scores discussed above. The highest point (4) on this screen indicates a full four-point matching of an individual's interest patterns with the grouping of vocations characteristic of the A physicians (high for Lawyer and C.P.A., low for Printer and Mathematics Physical Science Teacher); the intermediate points (3, 2 and 1) indicate matching this grouping in 3, 2 or 1 of these categories. And the lowest point (0) indicates matching in none of these categories. Points 4 and 3 on the screen (matching weighted toward the characteristic A physician constellation) would be expected to predict A physicians. Points 1 and 0 on the screen (matching weighted toward the characteristic B physician constellation) would be expected to predict B physicians. Point 2 on the screen (weighted equally between characteristic A and B patterns) would not be predictive. (Table 2.)

As indicated, this screen was originally developed from the Strong Test scores of 26 physicians on whom our original studies of styles of clinical transaction were based. To check the predictive accuracy of this

TABLE 2

ACTUAL PREDICTIVE CHECK ON PREDICTIVE VALUE OF SPECIAL STRONG
VOCATIONAL INTEREST SCREEN ON NEW GROUP OF 24 PHYSICIANS

Predictive Screen (high score Lawyer, C.P.A. low score Printer, MPST)		Actual Number of Physicians qualifying as:		Accuracy of Prediction
Scale	Predicts	A	B	
4	A	5	1	5/6 or 83%
3	A	3	1	3/4 or 75%
2	A or B	2	2	
1	B	2	5	5/7 or 71%
0	B	1	2	2/3 or 67%

screen, another group of 24 physicians was used. Strong test scores were available on each of these physicians. Predictions were made on each of them, using the screening device, whether they would achieve improvement rates of 68% or more with their schizophrenic patients, or not. When these predictions were then compared with the actual improvement rates achieved with schizophrenic patients, the A predictions turned out to be 80% correct and the B predictions 70% correct. More concretely, out of 10 physicians predicted to meet the A criterion, only 2 failed to do so; out of 10 physicians predicted to fall below this criterion, 7 did so.

These results thus constitute a check supporting the validity of the differences between the interest patterns of A and B physicians observed in the first study. They also support the idea that crucial determinants of success in the treatment of schizophrenic patients lie in the physicians. The cluster of interest patterns represented by high scores for Lawyer and C.P.A., and low scores for Printer and Mathematics Physical Science Teacher presumably contain clues pointing to special qualities in the physician's personality more likely to evoke favorable clinical response from schizophrenic patients. And the inverse constellation of interest patterns presumably point to special personal qualities less likely to evoke acceptance as an effective working partner. Thus compatibilities and incompatibilities between physicians and patients become relevant frameworks of reference for studying the intrinsic nature of the recovery process.

One possibility to be explored is that in-

dividuals represented at the extreme points of the scale comprising this screening device operate from an idiosyncratic stance in their attitudes and values and temperamental disposition in dealing as a person with their fellows; and that each stance is different from the other in some significant way which can be characterized, and brought into relevance to the schizophrenic patient's attitudes and expectations.

DEVELOPMENT OF A SECOND PREDICTIVE SCREEN

In order to explore this possibility further, and to attempt a more detailed characterization of the personal qualities of A and B doctors, it was decided to examine their responses to each of the 400 items composing the Strong Inventory. As an initial step in this procedure, a comparison was made between the actual responses (Like, Indifferent, Dislike) of the original 15 A and 11 B doctors to each item. By this procedure, 23 items were found out of the 400, to which A and B doctors gave contrasting responses at levels of statistical significance of between .02 and .05 by the Chi Square test.

Responses characterizing the A doctors (but not the B's) and those characterizing the B doctors (but not the A's) are listed in Table 3. On the basis of these findings, an 11-point screening device was then developed, embodying the 10 starred items in the Table. The highest point of this screen indicates a matching with characteristic A responses on all 10 items. The lowest point on the screen indicates a matching with characteristic A responses on none of the 10 items (i.e., a matching with characteristic

TABLE 3

CHARACTERISTIC RESPONSES TO INDIVIDUAL STRONG VOCATIONAL INTEREST TEST ITEMS WHICH DIFFERENTIATE 15 KNOWN A PHYSICIANS FROM 11 KNOWN B PHYSICIANS. DIFFERENCES ARE AT LEVELS OF STATISTICAL SIGNIFICANCE OF BETWEEN .02 AND .05, BY THE CHI SQUARE TEST. (THE * INDICATES ITEMS USED IN CONSTRUCTING THE PREDICTIVE SCREEN WHOSE PERFORMANCE IS SHOWN IN THE NEXT TABLE.)

<i>Responses Characterizing the A Doctors (But Not the B Doctors)</i>	
"Like"	*311. President of a society or club *365a. Many women friends
"Yes"	367. Accept just criticism without getting sore 375. Can correct others without giving offense
"Dislike"	59. Marine engineer *60. Mechanical engineer *68. Photoengraver *90. Specialty salesman 94. Toolmaker *185. Making a radio set
"No"	*368. Have mechanical ingenuity
<i>Responses Characterizing the B Doctors (But Not the A Doctors)</i>	
"Like"	17. Building contractor *19. Carpenter *87. Ship officer 121. Manual training 122. Mechanical training 187. Adjusting a carburetor 189. Cabinet making 216. Entertaining others 218. Looking at shop windows
"Dislike"	151. Drilling in a company 290. Interest public in a new machine through public addresses *381. Follow up subordinates effectively

B responses on all 10 items.) The middle point on the screen indicates an equal number of A and B matchings. And points above the middle (upper zone) indicate the net weighting toward A responses; while points below the middle (lower zone) indicate a net weighting toward B responses.

When this screen is used as a predictive

device, the upper zone would be expected to predict A doctors; the lower zone would predict B doctors; and the middle point would not be predictive.

As indicated, this screen was developed from the responses to individual items on the Strong Inventory of the original 15 A and 11 B doctors on whom our early studies of styles of clinical transaction were made. To check the predictive accuracy of this screen, the second series of 24 physicians was again used. When this was done, as shown in Table 4, it was found that the upper zone of the screen performed with 83% accuracy in predicting A doctors. Specifically, out of 12 doctors predicted to meet the A criterion only 2 failed to do so. Likewise, the lower zone of this screen performed with 78% accuracy in predicting B doctors. Specifically, out of 9 doctors predicted to fall below this criterion, 7 did so.

It is thus apparent that this second screen, based on only 10 out of the 400 items on the Strong Inventory, performs as a predictive device with even greater accuracy than the first screen based on the final scores in four vocational categories.

These specific items, identified in one series of known A and B doctors, and cross-validated in a second series, thus provide another set of leads for the task of attempting to characterize special personal qualities distinguishing A and B doctors, to whom schizophrenic patients make such a different clinical response.

ANOTHER VALIDATION STUDY

These findings seem to point quite convincingly to the presence of two opposite sets of qualities in the personalities of the A and B doctors, presumably relevant, perhaps crucially so, to the marked differences in their therapeutic results with schizophrenic patients. At this stage in the studies, the following important questions arise: are these results particular in some way to the special psychiatric milieu and working points of view prevalent in the Phipps Clinic? Or do they have a more general validity—i.e., would doctors with the same differential personal characteristics working in *any* clinical setting with schizophrenic patients have the same kind and degree of differential therapeutic results?

TABLE 4

ACTUAL PREDICTIVE CHECK ON PREDICTIVE VALUE OF SECOND SPECIAL STRONG
VOCATIONAL INTEREST SCREEN ON NEW GROUP OF 24 PHYSICIANS

(Net excess of A or B matchings: number of A minus number of B matchings divided by 2)		Actual Number of Physicians qualifying as:		Accuracy of Prediction (Upper zone vs. lower zone)
Scale	Predicts	A	B	
+5	A			10/12 or 83%
+4	A	3		
+3	A	1		
+2	A	4		
+1	A	2	2	
0	A or B	1	2	7/9 or 78%
-1	B		3	
-2	B		1	
-3	B	1	2	
-4	B	1	1	
-5	B			

An obvious method for clarifying these questions is to make a study, comparable to that on the Phipps doctors, on a sample of doctors trained elsewhere and working with schizophrenic patients in a different hospital setting. If the same personal characteristics of the doctors were found to be highly associated with favorable or unfavorable therapeutic results as has been demonstrated with the Phipps doctors, the general validity of these particular variables as significant influences in the outcome of treatment would be supported.

One such study on a small scale has been made on data provided by a neighboring psychiatric hospital.⁴ This hospital is a completely separate institution from the Phipps Clinic, with its own residency training program which is psychoanalytically oriented, and with a traditional interest in the treatment of schizophrenic patients. Information on the improvement rates achieved by individual doctors treating patients in this hospital was available. Eleven doctors from this hospital were selected for study; 5 who had met the A criterion of improvement rate (68% or better), and 6 who had not met this criterion. Strong Vo-

cational Interest Inventory scores were obtained on each of these 11 doctors. On the basis of each doctor's responses, and scores, on this test, his position on the 5-point screen and on the 11-point screen was ascertained.

The results of this procedure, using the 5-point screen, are shown in Table 5. It will be noted that 5 of the 11 doctors fell in the middle, borderland group (2 A's and 3 B's) which is equally weighted between characteristic A and B scores, and so is a non-predicting zone. However, 6 doctors were located in either the upper or lower zones where an accurate predictive effect is expected. It will be seen that the direction of prediction was accurate in 4 of the 6 instances, or 67%. That is, of 3 doctors predicted to meet the A criterion, 2 did so; and of 3 doctors predicted not to meet this criterion, 2 failed to do so.

Thus, although the numbers are small, the direction of association between personal characteristics and level of improvement rate of physicians trained and working in a different psychiatric setting than the Phipps Clinic was similar to that demonstrated in the Phipps doctors.

This similarity is more strikingly shown by the use of the 11-point screen (Table 6). With this screening device based on 10 of the 400 items making up the Strong Inventory, the separation of A and B doctors

⁴ We wish to thank Dr. Joseph D. Lichtenberg (4) of the Sheppard and Enoch Pratt Hospital for his kindness in obtaining responses on the Strong Vocational Interest Inventory, and for cooperation in our studies.

TABLE 5

ACTUAL PREDICTIVE PERFORMANCE OF 5-POINT SCREEN ON 11 PHYSICIANS
WORKING IN ANOTHER PSYCHIATRIC HOSPITAL

-4	B			
-5	B			

in the predicted directions is clear-cut. It will be seen that on this screen, only 2 doctors fall in the middle zone (1 A and 1 B). Of the 5 doctors whose screen position, based on their test responses, is in the upper zone, and who would be expected to meet the A criterion in actual therapeutic results, 4 did so—an 80% level of predictive accuracy. And of 4 doctors who fall in the lower zone, and who would be expected *not* to meet the A criterion in actual therapeutic results, none did so—a 100% level of predictive accuracy.

These results, from this one study of a small sample of doctors trained and working in another psychiatric hospital than the Phipps Clinic, constitute supportive evidence of some general validity of the thesis

that the crucial determinants of therapeutic outcome with schizophrenic patients lie in certain personal qualities in the physician. The doctor, it would seem from these studies, is the important, even crucial, variable, in determining the outcome of treatment.

It would be useful to seek further corroboration of the general validity of these findings, by studies of other samples of doctors working in several other hospitals. It is hoped that in time such studies can be carried out.

INTERPRETATION

The empirical findings presented indicate that personal qualities in the physician are important factors in determining the clinical

outcome in the treatment of schizophrenic patients. They also provide clues as to the kinds of qualities associated with favorable or unfavorable outcome.

Certain inferences as to the meanings of these findings may next be considered. What meaning, for example, is to be found in the fact that doctors whose schizophrenic patients show high improvement rates are found by the Strong Test to have interest patterns resembling lawyers? Or that those whose schizophrenic patients show low rates of improvement are found by the Strong Test to have interest patterns resembling printers, and to be mechanically inclined?

One line of thought is that the A's, with interests resembling lawyers, have a problem-solving, not a purely regulative or coercive approach. This is acceptable to the resentful, boxed-in patient likely to respond to prescriptive pressures by more withdrawal, and to mere permissiveness by inertia. Much of the psychotic symptomatology and behavior of the schizophrenic patient, and the nature of the personal issues with which he is preoccupied, seem a direct expression of a special orientation toward authority as external and imposed. His classical inward experience of feeling "controlled" or "influenced" by outside forces both expresses, and is an indicator of his dominant concern with imposed authority. The B doctors, with attitudes resembling printers—black or white, right or wrong—are likely to view the patient as a wayward mind needing correction, an approach likely to alienate him further rather than intrigue him into hopeful effort.

By reason of a basic self-distrust, the schizophrenic patient does not live interdependently by give-and-take in personal leadership and in cultural expectations, but avoids involvement with others. In the A physician he would find the values of responsible self-determination more honored and exemplified than those of obedience and conformity—an emphasis providing an avenue of progress out of his own entanglements in mutinous commitments toward authoritative influences seen as imposed from external sources. The A physicians, in their clinical styles of transaction with schizophrenic patients, reveal a capacity to

be perceptive of the individualistic inner experiences of the patients, while themselves functioning in responsibly individualistic roles. And solutions to the patient's problems are worked out through collaborative exploration of possibilities, rather than in the model of authoritative instruction.

In the B physicians, in contrast, the patient would find an emphasis on value systems weighted more heavily toward deference and conformity to the way things are. The particular rigidity of attitude implied by their mechanically inclined interests and orientation toward precision and a rule-of-thumb approach probably constitutes an actual hindrance to the development of self-trust and social spontaneity in the schizophrenic patient.

Physicians whose attitudes tend to expect and respect spontaneity tend to evoke self-respectful social participation more effectively than those whose attitudes tend to restrict spontaneity by preference for conventionalized expectations. This appears to be the basic difference in attitude between A and B physicians. The doctor whose attitudes to social situations are like those of the lawyer, who assumes that there is leeway for solving individual problems and for achieving individually desired goals within reasonably broad interpretations of society's rules and family expectations has the better prospect for opening up for the patient possible appealing prospects, of discovering personal problems rather than mere frustrations, and thereby eliciting more problem-solving effort and participation in life.

Although the emphasis in this discussion has been on contrasts between A and B physicians, it is evident from the data that considerable overlapping occurs and that there is a borderland group suggesting that a physician might move from a B position to an A position, if appropriately informed and motivated. There is some evidence in our data that shifts of this sort do occur, and that guidance along the lines of interpretation which have been presented does improve the therapeutic effectiveness of physicians with their schizophrenic patients.

REPORT ON THE SEMINAR PROJECT FOR TEACHERS OF PSYCHIATRIC AIDES¹

GARLAND K. LEWIS, R.N.²

The Seminar Project for Teachers of Psychiatric Aides, co-sponsored by the National League for Nursing and the American Psychiatric Association, has been in operation two years. A total of 18 two-week seminars have been conducted in the 4 states chosen for the pilot area: North and South Carolina, Arkansas, and Tennessee. One hundred and seventy-five nurses completed the seminars. The number of nurses attending from North Carolina (90) was greater than the combined number (85) from the other three states. In one state 35 nurses who had applied for the seminar could not be included because time did not allow staff to remain longer in that state. One other state had 4 nurses who could have attended if time had permitted staff to remain for further seminars. Two states were unable to fill the quota of students for each seminar. This was due in part to a smaller number of nurses employed in these states, as well as reluctance on the part of administration, both nursing and medical, to release their nurses for the two-week period. Also, the seminar staff was unable to visit the individual hospitals prior to conducting seminars, which might have helped to increase interest.

Sixty-nine and one-tenth percent of nurses attending seminars were employed in state hospitals, 15.4% in VA hospitals and the remaining 15.5% were from university, private psychiatric, and general hospitals, or were special students.

The majority (64.5%) of the nurses were under 40 years of age, and the remaining 34.7% were between the ages of 41 and 65. The project, as indicated by the title, originally was intended for nurse instructors of psychiatric aides. Since so few hospitals provide an instructor for aides, the majority (76.5%) of our students enrolled were head nurses (44.0%), and supervisors (32.0%), in-

asmuch as they assumed the major responsibility for teaching aides.

Several interesting aspects regarding the amount of clinical experience of the participating students were noted. It was thought worthwhile to examine the students' backgrounds by age groups in relation to their educational preparation, length of psychiatric experience, job title and number of patients for whom the nurses were responsible. This information was sought to ascertain the feasibility of the individual nurse's ability to teach aides as related to her work assignment. Sixty-one nurses were 21-30 years of age. The average length of experience for this group was 2½ years. Thirty-three of these were head nurses and each was responsible for an average of 185 patients. Fourteen of these younger nurses were supervisors and supervised an average of 572 patients per nurse. Six of the head nurses and supervisors had not had an affiliation or any preparation in psychiatric nursing. It is obvious that young nurses are carrying a tremendous responsibility in relation to their amount of experience and preparation. Older nurses carried even heavier responsibilities in terms of numbers of patients.

The purpose of the seminars was to give nurses working in all mental hospitals an opportunity to improve their understanding of the mental patients, improve nursing care, and learn new approaches in teaching psychiatric aides. Students were required to work directly with patients to give them first hand knowledge about the kinds of problems psychiatric aides deal with daily. Group and individual discussions were held with the seminar instructors to broaden the students' knowledge about the nursing care of the psychiatric patient. Specific emphasis was placed on the ways in which the principles of psychiatric nursing can be taught to aides.

The most outstanding positive result from the experience in the seminars seems to be the nurses' increased self confidence. Many

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² The National League for Nursing, 10 Columbus Circle, New York, N. Y.

of them had no previous preparation in psychiatric nursing, and had not worked directly with a patient recently, if ever. Many nurses indicated that for the first time they felt they knew what they could do for patients and aides and were more secure about their functioning. This is not surprising when you consider that 37% of the total sample had had no preparation in psychiatric nursing. However, 44% of the total group had had an affiliation in psychiatric nursing during their basic nursing education, but this did not necessarily mean the nurse had worked closely with patients during her affiliation. Eighteen percent of the nurses were graduates of a state or private psychiatric hospital school of nursing.

In an attempt to ascertain the nurse's ability to teach psychiatric aides how to improve the care of their patients, the seminar staff conducted one day follow-up conferences for each seminar group (except in one state where time did not permit). Almost all of the nurses attended these conferences, and participated fully. The staff met with the groups and allowed them to volunteer information about their work, only asking specific questions if they had not been brought out in the voluntary discussion, *viz.*, what kind of help do you now need, and what has been the reaction of aides, other nurses, supervisors, and physicians, to your work, *i.e.*, what kind of support or lack of it have you received?

In general, the kinds of problems they mentioned fell into three main categories: 1. Administrative, 2. Teaching, and 3. Nursing care problems.

In one state the first 6 seminar groups discussed many problems related to *administration*. These concerned work loads, rotation, shortage of personnel, and interstaff relationship problems. The latter related to trying to interpret to nursing and medical administration what they were attempting to do. The last three groups in this state barely mentioned these problems, and focused mainly on nursing care problems. Many of the nursing supervisors had attended seminars by the time these last groups met, which may account for the decrease in administrative problems.

In another state, two seminar groups did not mention administrative problems of any

kind, even though the staff was aware of their many problems. The other two groups in the same state indicated the extreme lack of communication between them and all supervisory personnel, and the lack of support from anyone.

In a third state the nurses from state hospitals indicated they had not worked with aides because of the shortage of personnel. Nurses from general hospitals indicated that they had worked with aides on their units, but they had no support from anyone in nursing service. The nurses felt this was due to the fact that all other nurses in the hospital were critical of the psychiatric service. The psychiatrists however, gave the nurses more responsibility and freedom and encouraged them to work with aides. The nurses from VA hospitals indicated they had worked with aides and nurses, and had full support from nursing service.

Teaching problems as presented by the students from all three states centered around two areas. The first, their attempt to change the aides' attitudes about patients, *i.e.*, that patients were ill, and their behavior was a part of their illness, and not a conscious deliberate attempt to misbehave. The second area concerned specific nursing care problems. The nurses requested further assistance in handling specific behavior problems which their lack of experience and help had prevented them from doing.

One major problem which was common in all states was the resistance from aides who had been employed 15 to 20 years. The resistance ranged from indifference to overt refusal to participate in any way.

In one hospital, the nurses' greatest difficulty was to try to change aides' attitudes and behavior regarding physical violence; *e.g.*, throwing ice water on uncooperative patients and keeping clubs on the ward to threaten patients.

In all three states nurses indicated that they had no problems with the majority of younger aides who were eager and interested in learning and requested assistance. In one hospital the supervisory aide of the male service was in charge of the nurses and this presented unique problems.

At the beginning of the second week of each seminar the nurses were given written directions about aide assignment to assist

them when they began their work with aides. Four to six weeks following their return to their respective hospitals, the nurses were mailed follow-up forms at 2 month intervals, to be returned to the seminar staff within a specified time. The forms were designed to give information about whether or not the nurses had attempted to teach aides, the kind of work they did with them, and their ability to increase their contacts and directly teach more aides. The percentage of forms returned varied for each seminar group. The number of returns of the first follow-up forms ranged from 33.3% to 100%. The returns of the second follow-up forms were less: 1.8% to 87.5%. It was difficult to ascertain accurately the numbers of aides nurses had worked with directly, but from both returns the nurses indicated that they have worked with 364 aides individually. Sixteen nurses indicated they worked with groups of aides, or aides on their wards, but did not indicate the number of aides in each group. We know that some groups contained two or three aides and others as many as 12. Thus 364 aides have been assisted by the nurses individually plus 16 groups of varying sizes.

Many factors have contributed to this variation. Account must be taken of the individual differences among the nurses. Some nurses had less educational background in psychiatric nursing than others, some were older and found it difficult to change their behavior. There was also a marked variation of experience of the individual nurses. In other instances the resistance or lack of it from nursing and medical administration varied. A further factor was the cooperation or resistance encountered from the aides themselves.

A questionnaire sent to all directors of nursing revealed that the total number of nurses employed in the 10 participating state hospitals was 277, while the number of charge aides, *i.e.*, aides in charge of one or more wards, was 597.

The follow-up conferences of each seminar, as well as written follow-up forms, indicated that many of the nurses were able to work more directly with aides and had instituted new methods of assisting aides as a result of the seminar.

A sociologist was employed to conduct a

follow-up study on the 90 nurses participating from one state. All levels of personnel in the hospitals were interviewed to ascertain changes in the nurses' functioning. This particular group of nurses was chosen since it had been at least one year since they had attended seminar and time did not permit a follow-up in the 3 other states.

A preliminary review of the follow-up assessment by the sociologist confirms the enthusiasm which the seminar generated in most of the nurses who attended it. There are indications that some nurses in each of the hospitals which were studied changed their administrative behavior and their mode of dealing with patients. Changes in dealing with patients—reported by nurses and corroborated in varying degree by attendants and physicians—include an awakened individualized interest in patients, and a lessening of covert apprehensiveness about interacting with disturbed patients combined with recognition of the nurse's own reaction to patients. In their administrative activities certain seminar graduates have made conspicuous changes, largely as a result of this learning experience. These include lessened rigidity and resistance to therapeutic innovations which others have attempted to foster, amelioration of specific conditions which were discussed during the seminar, and initiation of organizational and milieu improvements geared toward more vital patient care. It must be noted that the number of persons involved in such aspects, especially the initiation of organizational changes, is small; yet it is noteworthy that the improvements initiated or, at least, facilitated by these individuals have been copied by other hospital personnel—thus being precedents for further advancement.

There appears to have been relatively little formal teaching of individual attendants beyond that specifically assigned to the seminar nurses. But there is evidence that considerable information, unstructured teaching of attendants was initiated through the seminar and continues to the present.

Several states outside the pilot area have wanted to send nurses to the seminars, or have requested that seminars be held in their states. It was possible to include one nurse from Kentucky and one nurse from the National League for Nursing staff.

The Florida State Board of Mental Health has made plans to duplicate the seminars for nurses working in general hospitals with psychiatric units. A Veterans Administration hospital in the pilot area is conducting a series of one-week seminars in their hospital. The nurses who attended the seminars are teaching those who were unable to attend. Another VA hospital is planning a teaching program similar in nature. The Southern Regional Education Board has evidenced interest in continuing a pro-

gram similar to the Project in the 14 states of this area.

The National Institute of Mental Health, which financed the project, granted an extension of 5 months to prepare for publication, a report of the findings of all phases of the Seminar Project.

Recommendations from the report regarding implications for future projects, will be submitted to the National League for Nursing and the American Psychiatric Association.

THE CONSUMPTION OF ALCOHOL AND THE HYPOTHESIS OF RECIPROCAL COMPLEMENTARITY

A. H. HOBBS, PH.D.¹

For centuries man has speculated about phenomena associated with the consumption of alcohol. In comparatively recent years research findings have eliminated some old myths but have also, sometimes, given rise to new inconsistencies if not downright contradictions. This analysis is an attempt to show that at least some of these inconsistencies can be clarified by interpreting such phenomena within the context of a causal nexus rather than by direct cause-and-effect.

The need to describe human reactions as functions of a circular causal nexus rather than as the products of direct cause-and-effect will become apparent, I believe, as some of the inconsistencies in the interpretation of phenomena associated with the consumption of alcohol are cited.

INCONSISTENCIES AND CONTRADICTIONS ASSOCIATED WITH DRINKING

1. In human functioning, alcohol acts both as a stimulant and a depressant. A variety of evidence indicates that the consumption of alcohol depresses neurological functions; even to the degree that death results if a sufficient amount is consumed rapidly enough. Yet history and personal experience abundantly demonstrate that human reactions are stimulated by drinking. Such stimulation takes a variety of forms and varies to a degree which bears no constant relation to the amount consumed. Reactions vary all the way from hysterical gaiety to "crying in your beer." Some people begin to swing from the chandeliers after a few drinks while others steadily and calmly consume drink after drink with no observable effect until, perhaps, they fall flat on their face when they try to stand up!

One problem, then, is how to explain the contradiction of neurological depression and social stimulation. How, furthermore, can the wide range in variety and degree of

stimulation from the same quantity of alcohol be consistently interpreted? Why does the same "cause," in the form of the consumption of a given quantity of alcohol, have such a variety of effects?

Many similar inconsistencies and contradictions could be elaborated on but, for brevity, others will be merely listed, and only a few will be analyzed with the technique of the causal nexus.

2. Alcohol is, and is not, a food.

3. Alcohol does not add to your weight, but drinking can make you fat.

4. Alcohol does not dehydrate you, but it does make you thirsty.

5. The consumption of alcohol may increase sexual desire, but it detracts from sexual performance.

6. The effects of drinking are physiological, but just as truly they are mental and social as well.

7. Alcohol apparently is not habit-forming, but people do become addicted to drinking.

8. Chronic "alcoholism" is a medical condition and a psychological state of mind, but it is most successfully treated as a moral and ethical problem.

9. The most highly trained and skillful psychiatrists usually fail in their attempts to treat chronic alcoholics but the most stupid skidrow bum may contribute vital help in treatment.

Some modern studies attempt to resolve such contradictions by describing drinking as a strictly cause-and-effect, quantitative phenomenon(1), contending that intoxication occurs only when the concentration in the blood reaches 0.15%. Proceeding on this unrealistic assumption, "scientific" formulas have been developed to delineate precisely the amounts of various alcoholic beverages needed to produce this concentration. According to these formulas, it is extremely difficult to get drunk, and our modern "scientific" research has now established that it is impossible for anyone to get drunk on beer!

¹ Assoc. Prof. of Sociology, University of Pennsylvania, Philadelphia 4, Pa.

THE HYPOTHESIS OF RECIPROCAL COMPLEMENTARITY (2)

The argument here presented is that most such inconsistencies can be clarified by thinking in the context of a causal nexus which is part of the process of interpreting human reactions in accordance with the Hypothesis of Reciprocal Complementarity.

Based on evidence from muscular, glandular, and mental functioning, the hypothesis of reciprocal complementarity views human reactions and relationships as patterns of circular causality which can be initiated, facilitated or inhibited by any one of the several elements involved; these being muscular functioning, glandular and other chemical influences, mental coordination and mental imagery, and external stimuli, including moral codes and ethical precepts.

Since the higher levels of the brain have the capacity to fit reactions into a pattern which is meaningful in terms of the external environment as well as in terms of the internal environment of the body (3, 4), their functioning in the form of conscious thought is one of the elements which can initiate, facilitate, or inhibit human activity. With this capacity, the individual is an active determining agent in his responses rather than a puppet at the mercy of unconscious drives or of unthinking indoctrination through sub-cortical conditioning. As brain (mind) and muscles and glands (matter) are functionally interrelated, so too is the brain and the moral substance of the environment, the social controls.

External Homeostasis. In a fashion similar to the process by which the various parts of the brain coordinate muscular and glandular internal reactions to keep them in balance which is called *homeostasis*, so the higher levels of the brain strive to coordinate, to make balanced patterns of the moral codes and ethical principles which constitute the social controls. Homeostasis exists in relation to the external social environment as well as in relation to the internal milieu of the body.

Incomplete and Unbalanced Homeostasis. The higher (neopallial) levels of the human brain have the capacity to coordinate internal drives and external social imperatives into patterns which are mean-

ingful in terms of both, fusing the internal homeostasis with the external into intellectually satisfying, emotionally gratifying, socially responsible behavior. Yet the very complexity of these neopallium levels also endows human beings with a capacity to form patterns which are meaningful to the internal tensions of muscles and glands but inconsistent with the social controls, and *vice versa*. Or, the patterns may be crazily inconsistent with both internal and external conditions. Illustrative of the first unbalanced situation would be the rationalization of unchained lust or unbridled brutishness.

A situation wherein external homeostasis is attained at the expense of internal homeostasis would occur when the realities of the internal drives are smothered by arbitrary conventions which deny their existence. Another aspect of the interpretation is that elements of reaction which are separately antagonistic (such as the incorporation of the social controls in the neopallium *versus* the impulses toward emotional reactions which apparently are coordinated in the hypothalamus) combine in reciprocal and complementary relationships to form new functional syndromes of reaction. An example would be the sentiment of love.

In this interpretation, chronic alcoholism, mental disorder, drug addiction, criminality and other socially defined aberrations are a function of imbalanced homeostatic reactions.

INTERPRETATIONS OF CONTRADICTIONS BY RECIPROCAL COMPLEMENTARITY

The contentions which follow are tentative and need more proof though, for brevity, they are stated as positive assertions.

How can alcohol be, at the same time, a stimulant and a depressant? This seeming paradox is resolved if we recognize that the human brain is an evolutionary product. Various parts developed at different stages of evolutionary development. These different parts have different functions (sight, hearing, the rinencephalon or "nose brain" to coordinate activity associated with odors; the coordination of muscular functioning, glandular functioning, etc.). Many of these functions are superficially antagonistic, but the separately antagonistic mental processes

combine in reciprocal and complementary fashion to form functional syndromes. The neopallium of the cerebral cortex is the most recent brain development, hence the most sensitive to stimuli. Functioning in reciprocal and complementary relationship with the lower and earlier developed portions of the brain which coordinate emotional drives, it acts as an intermediary between these lower levels and the external environment(3, 4).

Surgical and pharmacological evidence (5, 6)—together with the testimony of thousands of years of civilized living—indicates that in humans the neopallium has the capacity to coordinate and make meaningful patterns of the moral codes and ethical principles necessary to social life. In a sober state, stimuli conducive to emotional expression from the lower (hypothalamic) levels of the brain must be fitted into these neopallial patterns.

The depressant effect of alcohol is selective, acting first on the most recently developed and most sensitively delicate neurological connections; those which collectively incorporate the pattern of the social controls. With these functions weakened, impulses for emotional expression from the hypothalamus, while absolutely constant, become relatively stronger.

Depending upon his characteristic temperament and his mood of the moment, the drinker becomes gay or gloomy, friendly or aggressive, argumentative or amorous in a measure which exceeds his sober state. Varying degrees of emotional stimulation depend upon the consistency and cohesiveness of the patterns of social control relative to the strength of the emotional urges, and are a function of the rate of absorption of alcohol into the system.

One factor which affects this rate of absorption is the presence or absence of food in the stomach; thus the "lift" from pre-dinner cocktails.

As more alcohol is absorbed, and as time passes, the depressant effect spreads to phylogenetically older levels of the brain affecting first the finer degrees of motor coordination, then gross muscular control. As the speech and visual centers in the brain are affected, speech becomes slurred, vision blurred and motor control lessened.

The same quantity of alcohol has different effects, even upon the same person, dependent upon his mood, the food in his stomach, and his general health. Also, an identical quantity has different effects according to the rhythm of drinking and the passage of time. A given quantity which produces a "lift" early in the drinking fails to give a comparable lift later in the drinking process when the functioning of the lower levels of the brain has also been depressed.

Currently it is supposed that experience in drinking does not affect the rate or degree of the depressant effect of alcohol. It is contended that the experienced drinker subconsciously compensates for successive losses of coordination. He is more adept at covering up his condition than the novice.

Other inconsistencies can be similarly interpreted as an interplay between physiological, neurological and social factors in which no one factor can separately be said to be "the cause." Since I wish to stress distortions of homeostasis which are involved in chronic alcoholism, other seeming contradictions will be only briefly mentioned.

In caloric content, alcohol ranks among the richest of foods but, lacking vitamins, minerals and amino acids(7), it cannot replace tissue nor be stored as fat; so it is, and is not, a food. Alcohol is a source of energy, however, and thus food eaten in conjunction with drinking, not being needed for the energy which is now supplied by alcohol, may be stored as fat. Similarly alcohol, having a strong affinity for water, draws it out of the cells of the body and brain, and while the total quantity of water is not reduced (that is, the physiological factor is constant) we still, psychologically, feel thirsty.

Through depressing the pattern of social controls in the neopallium, alcoholic consumption relatively increases sexual and other emotional urges. Since the sexual reaction necessitates a high degree of muscular coordination, however, the performance deteriorates as the fineness of motor coordination is blunted.

Subconscious or conscious awareness that the pattern of social controls was distorted during drinking gives rise to guilt feelings

characteristic of hangovers. If the distortion was mild, it can be joked about as merely silly. In more extreme instances the pattern is ruptured to a degree which cannot be fitted into any sensible pattern of social conduct and the drinker has a "black-out" which expunges the incidents from his memory. During the hangover the neopallial levels have sloughed off the depressant effects of alcohol while the lower brain levels have not. Relatively, the social conscience is therefore acutely active. Since the oxidation of alcohol is a continuous process, the lower levels of the brain must continue to function, even during sleep, giving rise to a feeling of physical tiredness as well.

The most effective treatment for the hangover is also the most dangerous. Sooner or later, potentially chronic alcoholics make the discovery that a drink on the morning after works wonders. The efficacy of this homeopathic treatment probably lies in the fact that the caloric content of alcohol gives them an energy lift, while its depressant effect reduces the disparity of functioning between the hyperactive neopallial levels and the underactive lower brain levels, thus reducing the feelings of guilt.

Reasons for contradictions in the interpretation of phenomena associated with alcoholic consumption are the temptation to quantify what is essentially a qualitative phenomenon, and efforts to reduce it to a psychological or even a physiological reaction. Such pedantic forays ignore the overwhelming historical testimony that drinking is essentially a social custom. This social role of alcoholic consumption has been most cogently expressed by my colleague, Professor J. P. Shalloo(8) :

Innumerable references may be found to the choice wines of Greece and Italy by such poets as Hesiod and Virgil. The literature of the Bible makes it clear that at least one of the more formidable figures upon occasion looked upon grape juice too long and too thoroughly but not too critically. Omar Khayyam immortalized the life-giving qualities of wine, while armies and navies were regularly served their rations of grog ; and near the Christmas season of 1940 King George dispatched 70,000 bottles of cognac to the Greek soldiers in Albania. In our times it is culturally imperative to toast the bride, christen the ship, seal the bargain, wel-

come the guest, speed the friend, salute the New Year, celebrate good fortune, wake the dead and even symbolize and ingest the blood of the Savior, through the medium of alcohol.

According to the hypothesis of reciprocal complementarity, a meaningful interpretation of drinking must include this social factor. Chronic alcoholism exists when the essentially social nature of drinking is subordinated to the consumption of alcohol as an excuse to evade social responsibilities.

Attempts to describe chronic alcoholism as a result of the frequency of drinking, the quantity consumed, or even as a function of the compulsive factor, all fail when we realize that most people who should be chronic alcoholics according to such categories, are not.

Now commonly accepted as a description of chronic alcoholism is one which is couched in social, rather than physiological or psychological terms(9) :

The medical definition of an alcoholic, as distinguished from the social drinker, is one whose drinking harmfully and definitely interferes with one or more of his important life activities. He may lose time from work due to drinking, or the quality of his work may suffer, or his homelife harmony may be disrupted, or he may so speak and generally conduct himself that his reputation and relationships with others suffer.

In a context of reciprocal complementarity, an alcoholic has disrupted the homeostatic balance between his emotional urges and the social controls. Subconsciously, he is aware of this distortion, as evidenced by gulping and sneaking drinks and far-fetched rationalizations for his drinking. At home his social guilt reveals itself as he becomes a "closet drinker." At parties, he graciously proffers to be "Mother's Little Helper," insisting that he, rather than the hostess, mix the drinks. He then proceeds to pour one for guest A, and one for himself ; one for guest B, and one for himself ; one for guest C, and a double for himself.

Later he engages in solitary drinking, drinking on lower social levels, bottle-hiding and finally, in the form of the binge, all pretense that his drinking is a social phenomenon is abandoned. I contend that the sole common denominator in the pattern of chronic alcoholism is the progressive in-

crease in the *self* factor in drinking and the concomitant decrease of the social factor. As this occurs, a neopallial pattern of rationalization to justify it becomes more firmly established. A social means to an end becomes a *selfish* end in itself.

Because this pattern of justification is on the cortical level of brain functioning, negative conditioning fails to correct it.

In the process of oxidation, alcohol goes through a phase in which it is converted into a toxic substance, acetaldehyde. Ordinarily the acetaldehyde is almost immediately converted into inert acetic acid. Thus another paradox: alcohol is a poison [toxic] but it is not poisonous. The term "intoxication" is a Nice-Nelly pseudo-scientific designation, far less meaningful than many social designations such as "drunk." Drugs such as Antabuse delay the conversion of acetaldehyde into acetic acid and permit it to accumulate in the system so that one drink makes a person violently ill. If theories of sub-cortical human conditioning had any appreciable validity (which apparently they do not—see reference 4) the alcoholic should soon develop a deep aversion to booze. Since the conditioning is sub-cortical, however, while the pattern which justifies his drinking is neopallial, such an approach is not likely to work.

Apparently a similar, perhaps identical process is involved in drug addiction(10) :

In the United States before World War I, patent medicines containing opiate ingredients were sold without prescription by pharmacists. Some women who took these medicines perhaps mistook the withdrawal symptoms for their illness, and as a result did not become addicted. But other women recognized and attributed their withdrawal symptoms to the remedy, and became addicted. In fact, during the 19th century women comprised about 60 percent of the addicts.

We see here that even in opiate addiction which, unlike addiction to alcohol, is physiological, the cerebral process plays an important role. A similar situation occurs with people who take physiologically habit-forming drugs in conjunction with illness. Most do not become addicts. Since addiction involves the neopallial levels of brain functioning, sub-cortical negative conditioning usually fails to remedy it(11) :

During recent years many alcoholics seek in sedative drugs a cure for their restlessness, nervous tension, and insomnia. Following a modern psychiatric practice, they take sedatives at night to make them sleep and stimulants, such as dexedrine by day, to wake them up. Their relief is only temporary, for within a few weeks their nervous tension and insomnia are worse than ever and their last state is much worse than it was before.

Similarly, psychoanalytic techniques seem to have little success in treating alcoholism. An interpretation of this failure would be that the analytic theory that excessive drinking is a substitution for repressed homosexual or incestual desires just does not make sense to the alcoholic(12) :

One has often seen these patients treated unsuccessfully by psychoanalysis. Even if the analysis reveals the genesis of his fears it does not cure them. It is only when he has accepted himself as an alcoholic and seeks a way of life that brings him serenity do the fears leave him.

Since neither the physiological nor the psychological (psychoanalytic) treatment enjoys much success one might, superficially, suppose that the problem of chronic alcoholism could be successfully attacked through the social factor in the causal nexus. This approach was tried in the "Noble Experiment," the 18th Amendment. Its failure can be attributed to the fact that an arbitrary imposition of the formal controls also fails to make sense in view of the long history of alcohol consumption and the ability of a majority of people to drink moderately.

Apparently the only approach to correcting the condition of chronic alcoholics which has any appreciable degree of success is Alcoholics Anonymous(13). Much of the success of AA, I believe, is due to the fact that the individual is treated as an active agent who participates in the reorganization of his own neopallial patterns. Also, the process involves a gradual reconstitution of the ruptured pattern rather than an arbitrary or all-inclusive one. First, the alcoholic must recognize, without any mental reservation, that no matter how ingeniously he justifies his drinking his thinking is wrong. He does not take a pledge to swear off drinking forever, but reaffirms his

resolution anew each successive day. Ordinarily he calls upon spiritual assistance to reenforce the fibre of his resolution, and is aided by the social fellow-feeling of others who have gone through a similar experience and who can look to him for help as he can call upon them. Though he stops drinking, he is still an alcoholic. He is a person who is unable to absorb the social controls into a meaningful neopallial pattern which is strong enough to maintain its consistency under the depressant effects of alcohol. He is a person whose balance between the individual urges and his patterning of the social controls is so delicate that it is seriously disrupted by alcohol. When so disrupted, he forms a neopallial pattern which virtually eliminates both the physiological and the social components and in which drinking becomes the psychological solution to all problems.

SUMMARY

Modern as well as ancient attempts to explain phenomena associated with drinking give rise to numerous inconsistencies. Such inconsistencies, I contend, can be resolved only by inclusion of the social factor.

The hypothesis of reciprocal complementarity is a technique which includes the social factor, both as external reality and as internally incorporated into patterns in the neopallium. Internal and external homeostatic equilibria are a function of patterns which involve these social elements as well as the functioning of other mental levels and physiological processes. In this interpretation chronic alcoholism is not, in principle, different from mental disorder (which also, now, is socially defined). Such and similar conditions can be interpreted as a disruption of homeostasis between individual urges and the social controls.

As these controls continue to expand and lose their definition (14) these imbalances, in one form or another, will increase. A

reduction in such pathologies might be ultimately attained through methods of child-rearing and education which contribute toward the formation of firm and consistent neopallial patterns of morality and ethics. Such patterns, however, must involve more than a patch-work of arbitrary conventions. They must, within the limits of the capacity of the individual, allow for expression of the integrity of the person as well as for maintenance of the social controls.

Meantime, some of the principles of AA treatment might, with profit, be incorporated into the therapy applied to mentally disordered patients.

RECURRENT PSYCHOTIC DEPRESSION ASSOCIATED WITH HYPERCALCEMIA AND PARATHYROID ADENOMA

MARTIN M. MANDEL, M.D.¹

Involuntional psychotic depressive reactions are commonly encountered in the fifth to seventh decades, but in many instances, organic causes for such reactions are overlooked. Mental changes associated with hyperparathyroidism, including depression, paranoid states, and schizophrenia have been reported by Barr and Bulger (1930)(1), Eitinger (1950)(3), and Fitz and Hallman (1952)(4). The occurrence of a recurrent depressive reaction associated with hyperparathyroidism and parathyroid adenoma during the involuntional period has not been noted previously, and the following case is reported to emphasize a less known organic cause in the production of depressive symptoms.

Case 1.—B. W., a 67-year-old housewife, was admitted to the Jefferson Hospital on November 1, 1958 with the chief complaint of depression of 2 months' duration.

She related that in 1949, 9 years prior to her present admission, she was treated for a severe depression which occurred following the illness of her daughter. She received a total of 12 electroshock treatments following which her symptoms cleared. She remained completely free of any depressive symptoms until September, 1958 when she developed guilt feelings because of her inability to care for her ill daughter and invalid granddaughter. She complained of persistent headaches, restlessness and loss of appetite. This was accompanied by a profound depression with periods of crying and agitation. She condemned her husband and family for their "lack of interest" in her illness. Upon one occasion she threatened suicide.

Of significance in the past history is a hysterectomy 7 years ago, as well as a partial resection of her tongue for a carcinoma in 1957.

Neurological examination was normal. Psychiatric examination revealed the patient to be withdrawn and completely lacking in spontaneity. She cried frequently during the inter-

view and felt that no one was interested in her problems. At other times during the examination she exhibited periods of agitation and excitement which were manifested by overtalkativeness and anger. No illusions or hallucinations were apparent.

Laboratory studies revealed a normal hemogram. Her urine was cloudy with a specific gravity of 1.012. There was a trace of protein present, but no sugar was evident by qualitative testing. Microscopic examination showed many clumps of leukocytes. A urine culture demonstrated the presence of *Escherichia coli* organisms in the amount of 50,000 organisms per cu. cm. of urine.

A diagnosis of psychotic depressive reaction was made, and she was given a total of 8 ECTs following which she exhibited a greater interest in ward activities. She was discharged on November 22, 1958.

She remained well until March, 1959, when her depression recurred together with symptoms of easy fatigability, constipation, frequency of urination, and mental confusion. She was readmitted to the Jefferson Hospital on March 20, 1959, and again a persistent urinary tract infection was noted. She was given 8 more ECTs and once again showed an improvement of her depression. An intravenous urogram was performed to further determine the cause of this urinary tract infection. It revealed the presence of a massive hydronephrosis of the right kidney with a large calculus in the pelvis of the right kidney. The blood serum calcium level was markedly elevated measuring 6.3 milliequivalents per liter (normal, 4.5) and the serum phosphorous level was 1.85 mgs. per cubic centimeter. An excessive amount of calcium was also present in the urine by qualitative testing.

A presumptive diagnosis of hypercalcemia secondary to parathyroid adenoma was made; and on June 18, 1959, an exploration of the parathyroid area was made. At operation, a large adenoma weighing 5 grams was found attached to the left inferior parathyroid gland. Her post operative course was uneventful with serum calcium levels measuring 4.5 milliequivalents per liter. There were no psychotic trends evident after the operation; and upon periodic examinations, there has not been a recurrence of her psychotic depression.

¹ Department of Neurology, Jefferson Medical College, Philadelphia, Pa.

DISCUSSION

Mental changes in hyperparathyroidism have been described previously by physiologists who encountered symptoms of depression, weakness, polyuria, and fatigability in patients having an excess of parathormone(2). Psychotic reactions, however, in these patients were rare and only a few cases of depression, paranoia, and schizophrenia were reported (1, 3, 4). The interesting feature concerning psychotic depressive reactions with hyperparathyroidism is that they produce symptoms which are indistinguishable from those exhibited by the rigid, compulsive, self-centered patient who is suffering from an involutional depression. Such was the case in this instance, for the presenting symptoms were consistent with the background of an involutional depression as was the clinical response with lifting of the depression after the electric shock. The recurrence of depressive symptoms 3 months after a second course of electro-cerebral therapy is to be expected in a psychotic reaction that subsequently was found to be present along with hypercalcemia, renal calculi, and hydronephrosis. This patient improved following parathyroid surgery as did other reported cases(3, 4).

From a physiologic standpoint, the high serum calcium concentration is believed to be responsible for the development of the psychotic reactions in hyperparathyroidism; although the exact mechanism is unknown (4). Greene and Swanson(5) reported a psychotic reaction in a hypoparathyroid patient who was overtreated and developed hypercalcemia. The calcium ion is known to depress the central nervous system when the level in the body fluids rises above normal(6). The reflexes become sluggish and the muscles become weak(6). Another side reaction of hypercalcemia is that of

decreased motility of the gastrointestinal tract which produces constipation(6). The symptoms of weakness, fatigability, depression, and constipation due to hypercalcemia can easily be misinterpreted as neurotic.

This case serves to emphasize the importance of excluding chemical causes of depression during the involutional period. The determination of the serum calcium level may be of value in the diagnosis of the less common psychotic reactions seen with metabolic and hormone imbalance, particularly hyperparathyroidism.

SUMMARY

A case of recurrent depression is presented in association with an adenoma of the parathyroid gland. The similarity between the symptoms of the involutional depression and those of hyperparathyroidism are frequently indistinguishable. Chemical factors should be excluded in recurrent depressive states and a serum calcium should be considered as a diagnostic aid in these instances.

THE OBSESSIVE-COMPULSIVE CHRONIC ALCOHOLIC

EDWARD PODOLSKY, M.D.¹

The obsessive-compulsive chronic alcoholic forms an interesting segment of the alcoholic population. This group usually consists of individuals in the middle-life period. With intensified fears, threats and frustrations, they tend to react with increased resentment and an intensification of all neurotic personality features. They resort to alcohol to overcome resulting intolerable tensions, by making some sort of adjustment to their overwhelming neurotic demands. This adjustment is of short duration, and when sober they become more rigid, ritualistic and laden with guilt feelings.

In the obsessive-compulsive, the symptoms, much like those of the other neuroses, arise from a conflict of the instincts. An attempted solution of the conflict results in symptoms which serve as a gratification of the instinctual drive. However, unlike other neuroses, the conflict in the obsessive-compulsive neurosis is not manifested in somatic complaints, but remains entirely in the psychologic sphere, by attaching the affect of the unconscious conflict to relatively innocuous ideas and activity.

Obsessive-compulsive behavior is in its general sense a repetition compulsion. This typifies all maladjustive behavior, and refers to the inability of neurotics to modify their behavior and the need that some of them have for alcohol in an attempt to effect such a modification. Obsessive-compulsive behavior in its specific sense is a peculiar neurotic syndrome. This refers to the ritualized symptom in obsessive-compulsive neurosis. This syndrome is unstable and represents a second line defense against some type of breakdown.

Obsessive-compulsive neurosis refers to a specific syndrome of symptoms which includes hand-washing or other pointless ritualistic behavior; compulsion to count or repeat certain words and phrases; obsessional fear of dirt, germs or of inadver-

tently harming another person. The obsessions are usually accompanied by ritualized precautionary behavior; the hands are washed a certain number of times a day and material must be arranged in a certain and particular way. These obsessions and compulsions are attempts to ward off guilt concerning unconscious sexual or aggressive wishes, or to undo or make reparation for them. The warding-off symptoms represent an attempt to avoid guilt-laden thoughts and to master them simultaneously.

Thus obsessive-compulsive neurosis can be said to be a secondary defense against a reactivation of repressed material, the seemingly pointless rituals serving to avoid the guilt implicit in the precariously repressed needs and fantasies.

As further breakdown occurs, symptoms may develop which are properly classifiable as hysteria, schizophrenia, paranoia, etc. The essential purpose of obsessive-compulsive activity is to ward off or prevent the onset of more serious symptoms.

Symptoms of this neurosis may include:

1. Compulsive rituals (e.g., hand-washing rituals).
2. Obsessive fear of dirt and germs (usually accompanied by cleaning and tidying rituals).
3. Obsessive rumination about trivial and irrelevant matters.
4. Compulsive need to count, or repeat verbal formulas.
5. Compulsive drive to work, or busy self in some activity.
6. Compulsive attendance to detail, often at the expense of the broader, more important aspects of the task.
7. Compulsive adherence to high standards of work, or morality, or to regulation.
8. Compulsive concern for orderliness and tidiness.
9. Compulsive pseudo-attempts at suicide.
10. Compulsive avoidance of feared situations (e.g., crowds) or obsessive fear of certain situations.
11. Compulsive habits or mannerisms (e.g., tics).
12. Obsessive concern with health.
13. Compulsive avoidance or obsessive fear of people.

¹ From the State University Alcohol Clinic, Dept. of Psychiatry, State University of New York, College of Medicine, Downstate Medical Center, Brooklyn 3, N. Y.

14. Obsessive fears of being poisoned, swindled or attacked.

15. Obsessive doubts, vacillations and worrying.

16. Compulsive sexual behavior (*e.g.*, masturbation).

17. Compulsive aggressive or emotional outbursts (*e.g.*, nagging or temper tantrums).

Compulsive behavior is never modified by experience; it is repeated time and again for no logical reason. The individual cannot help behaving as he does. Some unconscious force or tension compels him to express his repressed needs or conflicts in distorted form. All neurotic behavior, and much normal behavior, is compulsive in this general sense.

The obsessive-compulsive who resorts to alcohol does so in an attempt to moderate tensions, anxiety, and guilt feelings, to lessen the pressures of ritualistic behavior, to moderate the force of obsessive thoughts.

Case 1. P.J.M., Caucasian, married, 56-year-old male. He has always had an obsessive fear of dirt and germs, washing his hands innumerable times a day. He carried a cloth saturated with an antiseptic solution with which he opened doors, fearing to come in contact with the door knob. He ruminated about trivial matters, was hesitant in making decisions, would return several times after leaving the house to make sure the door was locked. He is employed as a bookkeeper, does his work efficiently, being scrupulously neat and exceedingly tidy.

Mr. M. began to drink at the age of 40. He would consume a quart of whiskey when he could afford it; at other times he would drink a gallon of wine. He found that drinking helped anesthetize his obsessive thoughts and moderate his compulsive actions and temporarily afforded him some relief.

Case 2. H.P.H., Caucasian, married, 42-year-old male. Compulsive activity consisted of counting and adding up license plate numbers, house numbers and other random numbers which he happened to encounter while in the street. It took him a considerable time to get anywhere if he had to walk. Riding cut down this time, but even then he had to take down as many numbers as he could. This, of course, interfered considerably with his everyday functioning. He was not able to hold down a job, and he drifted from job to job. One ritual that he had to perform every night before he went to sleep was to count the number of lighted

windows in a large apartment house near where he lived.

Mr. H. began to drink heavily at the age of 38, consuming a quart of gin in an attempt to moderate his compulsive activities. While intoxicated he was not so acutely aware of his number counting compulsions and in that way was able to obtain some degree of relief.

Case 3. G.S., Negro, married, 45-year-old female. There is a history of obsessive-compulsive activity of many years duration, with a compulsive concern for orderliness and tidiness; she was constantly getting her house in order, seldom leaving it for other activities. There may also have been a compulsive avoidance of feared outside situations, such as crowds.

Mrs. S. began to drink heavily at the age of 40, consuming a quart of whiskey during a drinking spree. She states that drinking helps free her, at least temporarily, from the steady grip of the obsessive-compulsive activity. "When I drink I am able to relax a little, something I cannot do when I am sober."

Case 4. L.B., Caucasian, 46-year-old married male. He had always had an obsessive concern about his health, carrying a variety of pills and tablets with him for imagined ills. Materials he was working with had to be arranged in certain ways. There was a compulsive need to count and add numbers he came across in his daily activities. He carried a paper bag containing one cigar and two boxes of matches. He did not smoke, but he felt that he had to have the paper bag with him to fend off accidents.

The patient was not able to drive his car over a bridge for fear he would be seized with an impulse to jump off. He would not go above 5 stories in any office building. He was constantly beset by doubts, vacillations and worries.

Mr. B. began to drink at the age of 40. Drinking, he found, helped dull his compulsive activity for a while. It helped to moderate his doubts and worries and thus was afforded some measure of relief.

Case 5. J.K., Caucasian, married 49-year-old female. Obsessive-compulsive activity consisted of hand-washing many times a day, taking 3 hours to prepare for bed, which consisted of taking 3 showers, arranging her hair in a very intricate manner. She would not have knives or scissors in the house lest she injure her children. She was afraid of having rope about the house; this suggested suicide.

She would not eat in restaurants, for fear

the cook might have not washed his hands. She would not pick up anything that fell to the floor for fear of contamination with germs and dirt.

Mrs. K. began to drink heavily at the age of 40, consuming a quart of whiskey during a drinking spree. Drinking helped to becloud her mind sufficiently to afford some degree of relief from her obsessions about suicide and homicide as well as to moderate her compulsive actions in constantly washing her hands.

SUMMARY

The obsessive-compulsive chronic alcoholic is characterized by :

1. Compulsive rituals and obsessive fears.
2. Rigidly controlled emotional reactions.
3. Hypochondriacal trends.
4. Rigid perfectionism of an obsessive-compulsive quality.
5. Compulsive pseudo-attempts at suicide and homicide.
6. Compulsive doubts and vacillations.
7. With intensified fears, threats and frustrations he resorts to alcohol in an attempt to moderate these intolerable feelings, obsessive thoughts and compulsive activities.

One of the objectives of therapy with the obsessive-compulsive chronic alcoholic is

the strengthening of the ego, building up his self-confidence. This is so, in spite of the fact that he has feelings of omnipotence. Generally, it has to be pointed out to him that the use of his defenses may be justified in principle, although it is desirable that some of his methods could and should be modified.

The object is to examine the patient's specific defenses quite minutely and their dynamics unveiled. Obviously, both therapist and patient search for more effective ways of dealing with urgent underlying problems. There should be an exhaustive discussion of the patient's hostility, and methods of channelling it along creative avenues should be undertaken.

How is the complicating factor of alcoholism managed? In most of the cases the use of tranquilizers, Thorazine, Miltown, Sparine, *etc.*, is of value in moderating the craving for alcohol. In the more severe cases Antabuse has proved very effective. In the therapeutic management of the obsessive-compulsive alcoholic it is essential to treat both the neurosis and the alcoholism. The combined psychotherapy-psychopharmacological program as above indicated has proved effective in most cases.

THE SIBLING RELATIONSHIP IN GROUP PSYCHOTHERAPY WITH PUERTO RICAN SCHIZOPHRENICS¹

EDUARDO D. MALDONADO-SIERRA, M.D., AND RICHARD D. TRENT, Ed.D.²

THE NEED FOR ADAPTATIONS OF TREATMENT METHODS

There can be little doubt that culture has a striking impact upon personality development(5, 7, 12, 15, 27, 32). By culture, we refer to a unique mode of social life based upon historical patterns of acting and thinking which reflect covertly and overtly organized feelings and perceptions held in common by all those individuals considered "normal" by the community. Culture influences the "normal" person and lends a distinctive coloring to the psychopathology of the abnormal. Recent literature in social psychiatry(1, 10, 27, 28, 39, 41) yields numerous descriptions of culturally-influenced, geographically restricted mental disorders such as *Hsieh-Ping* of Formosa, *Koro* of Malaya and *Arctic Hysteria*, a schizophrenic disorder suffered only by Eskimos and natives of Siberia. Here in Latin America, two somewhat similar, culturally influenced disorders have been identified: the *Susto* phenomenon of Peru and the so-called *Puerto Rican Syndrome*. The major symptomology of *Susto* or "magic fright," as characterized by Wittkower and Fried(39), included the patient's low threshold for anxiety toleration, hyper-excitability, state of depression with an accompanying loss of weight and the delusion that his "soul" had been separated from his body and had been kidnapped by the Earth.

Like *Susto*, the *Puerto Rican Syndrome* is characterized by overwhelming anxiety, bizarre seizure patterns, transient depersonalizations and regressions(29, 31). Not only does the cultural milieu create the conditions for its psychopathology and thus influence content, but also, as Henry(13)

has pointed out, certain methods of treatment may even tend to be consistently effective or ineffective when applied to mental patients representing different racial, cultural and societal backgrounds. While it is true that psychotherapists are becoming increasingly concerned with adapting treatment techniques to the needs of specific patients(33), recognition of the impact that a particular cultural milieu has upon the behavior, interpersonal transactions and attitudes of patients in psychotherapy is apparently a recent phenomenon. The Indonesian psychiatrist, R. S. Slamet Iman Santoso, indicated the difficulties of applying Western psychotherapeutic techniques to the Indonesian and touched upon in-therapy issues when he wrote:

The fact that we physicians learned psychotherapy as a Western concept, via a Western language, adds to the difficulty (of psychotherapy). Not everything expressed in English can be translated into some of the dialects. Nor do some Western concepts and ideas accord with Indonesian ones. In my experience only those persons who have absorbed much of Western ideas are suited to direct psychotherapy. These are few and even for them, though language is unimportant, some Western concepts must be modified to fit Indonesian ways of life . . . psychotherapy has a great future in Indonesia, but it must be guided by extensive anthropological study . . . (14).

It should be clear from the foregoing that the mere transplantation of treatment methods from one culture to another is fraught with questions of relevance, validity and reliability. What is sorely needed is the adaptation of therapeutic techniques for making what has been learned about American and European psychotherapies culturally relevant to other societies.

AN ADAPTED GROUP TREATMENT PROCESS

We have been working for the past 3 years with group psychotherapy for regressed, Puerto Rican schizophrenics, attempting to develop a group process more

¹ This investigation was supported by Research Grant No. OM-80 (R) from the National Institute of Mental Health, the Public Health Service. Read at the 35th Pan-American Medical Congress, Mexico City, May 4, 1960.

² Respectively, the Executive Director-Director of Research Programs and the Director of Research of the Puerto Rico Institute of Psychiatry, Bayamón, Puerto Rico.

culturally relevant for our patients. The method evolved and its rationale has been described in detail in a forthcoming publication (19).

The major feature of our method of group psychotherapy is the employment of a *three-member team* as therapists representing a healthy family group representing a mother, a father, and a sibling. The father figure is a senior psychiatrist; the mother figure, a mature psychiatric social worker; and, the sibling figure, a young first or second year resident in psychiatry. Our technique is based upon the theory that the re-creation of the family setting with father, mother and sibling surrogates will tend to reactivate earlier the encapsulated traumatic materials of the schizophrenic and to quicken the pace of therapy. While we are aware that our team of therapists was an artificial family for the patients in early sessions because of the lack of intimacy between members, it was presumed that the patients would be gradually stimulated to attach symbolic value to the therapists as parental and sibling figures and would act out their earlier conflicts with each.

Three groups of 8 patients each were selected on the basis of several criteria. Each patient had a confirmed diagnosis of schizophrenia. All were chosen from among our most regressed patients from "back wards." Each had been hospitalized for at least 5 years. In addition, all had previously received almost all the available therapies including individual psychotherapy, physical therapies, conventional group psychotherapy, social and occupational therapies. No stress was placed upon the kind of schizophrenics selected and our groups included paranoids, simples, undifferentiated and catatonic types.

The major techniques briefly summarized, included: (a) the development of conscious affect between a young psychiatric resident (sibling figure) and the group of patients by means of 3 to 4 weeks of play activities; (b) the gradual introduction of the 2 other therapists into the group; and (c) family-centered, group psychotherapy by the 3 therapists with their 8 patients, in order to give patients the opportunity to react to significant persons representing the members of a healthy family. The therapy

team members made consistent interpretations of the relations established with members of the group with the sibling acting as the patient's alter-ego.

The results of this adapted process have been gratifying. Changes in the patients' condition were assessed before, during and after therapy, employing independent psychiatric evaluations, projective testing, ward observation ratings, and a special research battery. Of the 24 patients treated: 11 were rated greatly improved and were discharged from the hospital; 7 much improved; and 6 showed little substantial improvement. A followup investigation of treated cases will begin in June 1961 and results will be reported.

As we have worked with this group process, the concept of the *sibling's relationship* with Puerto Rican schizophrenic patients appears to be an extremely valuable tool for overcoming the intricate difficulties of communication with these patients. The major purposes of this paper were three-fold: 1. To outline our rationale for the inclusion of the sibling as a member of the therapy team. 2. To describe the major maneuvers of the sibling in the team work. 3. To suggest that the employment of the sibling relationship may be a valuable feature of therapy for Puerto Rican and other Latin American schizophrenics.

RATIONALE

Many students of the Latin American family have observed that the Latin male tends to be a dominating authoritarian father figure (6, 11, 17, 23, 24, 37). This generalization is applicable to the Puerto Rican father (2, 26, 35, 40). For example, the anthropologist, Wolf (40), in an analysis of the roles of fathers in rural mountainous areas of the Island, pointed out that the fathers were strict, aloof, authority figures with castrating and threatening aspects. She also suggested that as long as the father was strong and healthy, his growing sons were robbed of much of their self-determination and developed rather dependent and resentful attitudes toward authority.

The Latin father's communication with his children tends to be limited and restricted to personal and non-taboo topics. Of perhaps greater significance is his lack

of communication with his wife. In summarizing an inquiry into problems of communication between husbands and wives on matters related to birth control among Puerto Rican lower-class families, Stycos and his colleagues said :

Male dominance leads some husbands to believe that the sphere of family planning is their prerogative alone, and makes wives reluctant to initiate conversation or action. Moreover, there is some evidence suggesting that when conversation does occur it tends to be one-sided ; i.e., the male talking, the female listening(36).

It can be said that the typical Puerto Rican male is constantly in need to reaffirm his maleness. His concept of maleness may even go back unconsciously to descriptions of heroic individuals in the Middle Ages : the cavalier, the nobleman, the *conquistador*. To be male means to be both authoritarian and domineering as well as a "Don Juan," for he is a firm believer and advocate of the double standard of sexual morality. In the course of proving his maleness, the Puerto Rican father may not be home very often after work for he prefers the company of his male friends or a mistress. However, despite his physical absence he is almost always psychologically present(36, 51).

The self-sacrifice and martyrdom of the Puerto Rican mother is essential to the unquestioned and absolute supremacy of the father. While the husband can exercise great freedom in his activities outside of the home, no such freedom is extended to the wife ; the roles of the married women tend to be restricted to home activities such as raising children and performing household chores. The married woman may be aware of her husband's extramarital affairs, but is expected "to suffer in silence." At an unconscious level, however, in our opinion the married woman often allays her thinly repressed hostility toward her husband through very passive-aggressive manipulations of the males in her family.

The significance in this pattern of family dynamics is that Puerto Rican children, as Wolf and others(20, 40) have pointed out, develop unconscious resentment toward male authority figures. Nevertheless, it appears that Latin males can not function efficiently without strong hierarchical au-

thority. Because of the authority of the father, when children are confronted with personal problems, they will tend to discuss their problems in a more spontaneous and confidential way with an older sibling or peer than with paternal figures. At the same time, however, the first-born son in the family is allocated much "unearned authority" and has more prerogatives than his younger siblings. It has been commonly observed that when a younger member of the family gets in trouble he tends to confide more in his oldest male sibling, who, according to our Latin pattern, is taken for granted as the eventual substitute or surrogate of male authority in the family when the father is absent. Perhaps the intimacy of the sibling relationship is a universal phenomenon in its application ; however, in Puerto Rico and other Latin countries, we would suggest that the sibling relationship is certainly exaggerated due to the conflict with authority.

The schizophrenics in our groups were Puerto Ricans all of whom had been exposed to the Island's family patterns and socialization process. Like the schizophrenic of other cultures, he is painfully distrustful and resentful of other people. This resentment may be due to the severe early warp and rejection he encountered from significant people of his infancy and childhood. As Fromm-Reichmann has so succinctly stated :

The schizophrenic's partial emotional regression and his withdrawal from the outside world into an autistic-private world with its specific thought processes and modes of expression and feeling, is motivated by his fear of repetitional rejection, by his distrust of others, and equally by his own retaliative hostility (which he abhors), as well as by the deep anxiety promoted by this hatred(9).

It is interesting to note that Slavson(33) cites a personal communication from the Argentinian psychiatrist, Dr. Krapf, to document his contention that Latin American patients display a great deal of initial diffidence, uncommunicativeness and resentment to male therapists. In our experience one of the greatest difficulties is to communicate with the schizophrenic at an emotionally empathic level. If the male therapist assumes a paternal role, the schizophrenic

will tend to react by muteness and withdrawal. If the therapist establishes a sibling relationship, feelings of trust and confidence which the patient once shared with his own brothers may be reactivated, facilitating communication and rapport. The sibling relationship is a deliberate therapeutic maneuver aimed at overcoming the schizophrenic's repressed resentment and massive fears of rejection from maternal and paternal figures. His previous sibling relationships do not appear to have undergone the same intense repression. They have been less threatening and have remained more conscious.

THE SIBLING'S MAJOR MANEUVERS

As indicated above, our adapted group psychotherapy begins with 3 to 4 weeks of play activities under the guidance of a male psychiatric resident who represents an older sibling figure. The resident was in complete charge of the 8 patients just as the older sibling is when the father is absent from the home. The major activities during these weeks include games, close-contact sports, picnics, swimming, trips off the hospital grounds and the like. To enhance in-group identification, the resident and patients wore special clothes—the same colored baseball caps, shoes, pants and shirts.

The resident attempts: 1. To get closer to the patients, to establish contact and communication; he begins building the *bridge* which will eventually bring the schizophrenic in interpersonal contact with mama and papa. 2. To gain some insight into the *unconscious* of the patients so that later in the course of therapy he may act as their spokesman or alter-ego. 3. To be able to introduce papa and mama into the therapy group in a way *consistent* with the traditional paternal and maternal roles of this culture.

The sibling is constantly with the patients for these weeks of play. He re-experiences part of his own childhood. He repeats attitudes and behavior toward the patients that he had shown toward his own brothers. He gives the patients material things: candies, refreshments, *etc.*, as brothers often do. He uses body language through physical activities; he deliberately employs sports and exercises as a common language

thus stimulating physical awareness of self. If the patients play poorly, he never criticizes them. He observes and notes the way they behave toward him and toward other patients. He quickly gains many insights into their personalities through their comments, fear, wishes, silences, facial expressions and bodily movements.

Almost all activities are carried out at a non-verbal level. When names are used, only first names or familiar nicknames are employed. Most conversations are in simple, matter of fact language. The resident becomes, in part, a child in the sense of the "childlike" schizophrenic.

A few days before the activity period is terminated, the two other members of the therapy team are introduced to the patients: a male psychiatrist (father figure) and a female therapist (mother figure). In the introduction of the father figure, he merely observes the group, speaks briefly to patients and leaves. Introducing the mother figure is associated with meeting the oral needs of the patients: she brings them cool drinks, candies, pudding, *etc.* Thus, some of the major cultural aspects of the traditional roles of the Puerto Rican mother, father and sibling are deliberately replicated by their introduction to the group and their maneuvers.

At the end of 3 weeks of intensive play and the introduction of the father and mother figures, the stage is set for the second phase: family-centered, group psychotherapy. To overcome the patients' initial diffidence, uncommunicativeness and other unconscious reactions to the paternal and maternal therapists, the sibling figure serves as the "loudspeaker" for the 8 patients. For example, in the first two sessions, the resident reported to the father figure the behavior and reactions of each patient during the activity phase. As sessions continue, the resident attempted to verbalize *concretely* to and for the patients what he perceived the patients themselves were feeling and thinking. In this respect, our sibling's maneuvers are similar to Rosen's (30) direct analytic procedure of talking directly to and about the patient's unconscious. We agree with Rosen that this technique helps the patient to understand more quickly the meaning of his psychosis as

well as to establish a meaningful communication system between patients and therapists.

It should be noted in reference to the sibling's group transactions and maneuvers that we do *not* employ the term, *role*, to describe the latter's behavior. To the present writers a *role* is a sociological term denoting specific socially defined and socially expected behavior such as one's age and sex roles (18, 32, 34). Further, *roles* are patterned in accordance with the value orientations of a culture and the behavioral transactions related to *roles* are concerned with the maintenance of interpersonal equilibrium within social units.

Likewise, we use the term, *sibling relationship*, rather than *sibling transference* in our descriptive summary of the sibling's maneuvers. Transference is a poorly understood term (3, 4, 8, 25, 30) and because of linguistic confusion one finds that the term is sometimes misapplied and misused.

The kind of relationship the sibling establishes with patients in our work is not transference, *i.e.*, our patients do not repress much of their earlier attitudes and feelings toward their siblings as is the case when parental figures were involved. In their relationships with the sibling figure, our schizophrenics repeat and relive primarily conscious attitudes which they have shown toward their own siblings in their past lives. What we are doing then is employing a typical, Puerto Rican family phenomenon (the closeness of siblings) as an asset in group psychotherapy for schizophrenics. Whether or not this maneuver would be an effective device for schizophrenics of non-Latin cultures, is a matter of speculation and future research.

SUMMARY

This paper summarizes *one* way a group psychotherapeutic process was made more culturally relevant for Puerto Rican schizophrenics. A three-member therapy team, representing the significant members of a family (father, mother and older sibling), was employed with each group of patients. Attention was focused upon the *sibling's relationships* in the therapy team and the ways in which the sibling's therapeutic maneuvers were employed in overcoming

the intricate difficulties of establishing meaningful communication with the patients. The sibling's transactions in verbalizing the unconscious of the schizophrenic to the mother and father figures results in a rapid resolution of resistance for what was formerly deemed dreadful and secret, and which through repeated sibling verbalizations gradually acquires the appearance of the commonplace.

CLINICAL NOTES

The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.

THE UNIQUE THERAPEUTIC PROPERTIES OF TRANLYCYPROMINE AND TRIFLUOPERAZINE (PARSTELIN)

BURTRUM C. SCHIELE, M.D.¹

The combined use of a CNS stimulant and a CNS suppressant has theoretical merit, particularly for individuals with mixtures of depressive and other symptoms such as fear, anxiety, or paranoid trends. The apparently opposing actions do not cancel each other out, as one might expect. Though the mechanisms of action are incompletely understood, each drug probably affects different "centers"; together they may exert a complementary or synergistic effect. A particularly effective combination is afforded by using tranlycypromine (trans-dl-2-phenyl-cycloproylamine, SKF-385)² as the CNS stimulant and trifluoperazine (Stelazine) as the CNS suppressant.

Tranlycypromine is the most potent monoamine oxidase inhibitor available. It has two unique properties which set it apart from other MAO inhibitors. First, it is a nonhydrazine. This may account for its apparent safety. (The hydrazine moiety may be responsible for some of the serious complications known to occur with some of the other stimulants). The second is its bimodal stimulating action. It has a rapid, direct action similar to that of the amphetamines to which it is related, and it also has the slow, cumulative, indirect action of the other MAO inhibitors.

We are reporting our experience with the combination tablet containing 10 mg. tranlycypromine and 1 mg. trifluoperazine which was used in the treatment of 96 patients.³ Two-thirds were outpatients; treatment varied from a few days to 6

months. The usual starting dose was one tablet in the morning and one at noon. Unless a favorable response was obtained or limiting side effects appeared, the total dosage was increased by one tablet every other day to a usual maximum of 6 tablets daily. Patient tolerance varies widely. Once satisfactory results are obtained, administration of the drug can usually be continued as long as necessary. Like the other MAO inhibitors, this compound has a cumulative action and the dose may have to be reduced for some patients.

The following clinical observations were made:

1. In most cases the medication either works promptly or does not work at all. Results were good in 59 cases, poor in 23, and equivocal in only 12.

2. Twenty-eight patients noticed dramatic relief from tension, depression, fear or depersonalization within a day or two. Inability to tolerate the drug was also discovered promptly. The prompt indication of its effectiveness in a given case is one of this drug's main virtues.

3. No serious complications of any kind were observed, but a number of troublesome side effects did occur. Increased insomnia was a limiting symptom, especially in 10 patients who already suffered from this difficulty; postural hypotension with dizziness occurred in 9; headache was noted in 4 patients and tremors of the extremities occurred after several weeks in 6 patients. These reactions responded to reduction of dosage. Overstimulation or sedative effect was rare.

4. Target symptoms were depression, retardation, fears, fatigue and social withdrawal. The use of this medication should not be limited to depressed patients, since it also appears to help many schizo-adaptive

¹ Department of Psychiatry, University of Minnesota Medical School, Minneapolis 14, Minn.

² Tranlycypromine will be marketed as Parnate and the combination tablet as Parstelin by Smith, Kline & French Laboratories, Philadelphia, Pa.

³ In collaboration with Dr. Alan Challman, Minneapolis, and Dr. Benjamin Lund, Mankato, Minn.

individuals; in fact, our most striking results occurred with certain "hard-core pseudoneurotic" schizophrenics. Frank schizophrenics may need additional phenothiazine medication.

This medication appears to be sufficiently promising to warrant additional investigation. We have therefore begun a double-blind study in order to determine further its clinical usefulness.

NEURAMINIC ACIDS IN THE CEREBROSPINAL FLUID OF SCHIZOPHRENIC AND OLIGOPHRENIC PATIENTS

GABRIELE CHISTONI, M.D., AND ROBERTO ZAPPOLI, M.D.¹

In a preceding note(1) we have described a new method for determining quantitatively neuraminic acids (NA) in cerebrospinal fluid (CSF). This method allows us to appraise both the free fraction and the protein-bound fraction of the NA, and, by means of anion-exchange resins, makes it possible to eliminate the certain cause of errors by doing away with the hexoses(2).

With this method we have determined the concentration of the NA in the CSF of 50 subjects (13 control persons; 13 oligophrenics; 11 cases of presenile, senile and atherosclerotic dementia; 13 schizophrenics). As we have pointed out(3), the total average concentration of the NA was lower in the 3 groups of patients than in the control subjects. Although the variations already met with in the above cases are of deep significance from a statistic point of view, we have considered it useful to continue our researches on a larger number of subjects, limiting, however, our observations to control persons, oligophrenic and schizophrenic patients.

RESULTS

We report here the results obtained in 76 subjects, divided into the following groups: 26 adult control subjects (12 men, 14 women); 26 oligophrenics (12 men, 14 women); 24 schizophrenics (10 men, 15 women).

The CSF of these subjects, who were submitted to the general laboratory examination (cells count, determination of proteins and sugar, paper electrophoresis, colloidal reactions, R.W.), were all normal.

Control subjects. The individuals belong-

ing to this group were admitted to our clinic for idiopathic cephalaea or cephalaea in consequence of a slight injury to the skull (subjects in whom it was presumed there was no damage to the nervous system). Ages ranged from 17 to 52. None showed any objective signs of neuropsychic trouble; the radiologic and electroencephalographic findings and ordinary laboratory tests were all negative.

The total NA quantity in the CSF of this group varied from 1.8 mg. to 5.3 p. 100 ml. with an average of mg. 3.08.

In 7 subjects in whom the free fraction too was determined, it was seen to be 75-94% of the total quantity.

Oligophrenics. Age range of the 26 oligophrenic subjects: 15 to 40. Nine had a pre-existing brain damage, from infancy; in the other 17 it was not possible to find a cause of the oligophrenia. The mental deficiency had been noticed in all cases at a very early age and was present in a high degree: 16 could be classified as idiots; 4 (ages respectively 15, 26, 38, 40) on the absciss of the Terman-Merrill scale, showed a mental age of respectively 3, 4, 6, 8 years; 6, according to the Wechsler-Bellevue scale, had an I.Q. below 60.

The values of the total quantities of NA in these patients were between 0.3 and 3.5 mg. p. 100 ml. The average of the 26 cases was mg. 1.77, that of the 9 cerebropathic subjects 1.57. In 5 patients of this group, in whom we also determined the free fraction, this was practically absent in 2 cases, in which the total quantity was 0.3-0.4 mg. p. 100 ml., while in the others 3. represented 75-86% p. 100 of the total quantity.

Schizophrenics. The patients in this group had not received any therapy for at least 4

Values, in mg. p. 100 ml., of the total quantity of Neuraminic Acids present in the cerebrospinal fluid.

σ = average square waste.

t = parameter of Student-Fisher calculated in comparison with the controls.

P = percentual of chance probability.

months. Eight were hospitalized for the first time. Their ages were between 17 and 42. The symptomatology was typical: simple schizophrenia (3 cases), hebephrenic schizophrenia (12), hebephrenic-catatonic (1), catatonic (2), paranoid schizophrenia (6).

The values of the total quantity of NA varied from mg. 0.9 to mg. 3.2 p. 100 ml.; the average of the 24 cases was mg. 1.84. In 5 patients of this group we determined both the total quantity of NA and the free fraction: the latter represented 65-83% of the total quantity (Table 1).

From these data we see that the NA concentration in the CSF showed ample variations in the three groups considered; keeping to the averages, the total quantity of the NA is less in the two groups of mental patients than in the control subjects: 43% less in the oligophrenics and 41% less in the schizophrenics. We have calculated on the basis of our data the parameter *t* of Student-Fisher, in order to determine if the differences between the average values met with in the single groups were statistically significant.

Comparing the findings of the normal subjects with those obtained from the oligophrenics and the schizophrenics, the value of the *t* was seen to be respectively 6.2 and 5.4. To those values correspond a *P* (casual probability) <0.001. The findings, shown in the table, are therefore statistically significative.

COMMENT

The further determinations of the total NA concentration carried out by us in the CSF confirm that in the oligophrenics and schizophrenics a quantitative diminution of these substances as regards normal subjects is present. As we have affirmed(3), such a variation is due essentially to the diminution of free NA, that is of the fraction not bound to the proteins.

The quantitative values obtained by us are proportionally about half of those reported by Bogoch(4). This difference is very probably due to the different method used: in his determinations the interference of the hexoses, which, as we have demonstrated(1), also react with the Bial's reagent, is not taken into account at all.

Although Bogoch's method is less pre-

cise than ours, his findings regarding schizophrenic subjects, agree with ours: he too has observed a considerable reduction of the NA total quantity in these patients in comparison with the control subjects.²

As to the interpretation of these variations, Bogoch, having noticed that the NA concentration in the CSF tends to augment in proportion to age, put forward the hypothesis that there is a ratio between the CSF NA total quantity and the maturation processes of the nervous system(4). According to him the NA have an important part in the functions of the ematoliquoral barrier. Cumings and coworkers(6) stated that the NA, inasmuch as they are components of the molecule of the ganglioside, a hydrosoluble glycolipide, are contained in the cerebral cortex and, in a minor quantity, in the white matter. They further report that the quantity of the NA in the grey matter does not vary perceptibly according to age, while in the white substance it gradually diminishes during the course of life.

Our actual knowledge of the NA metabolism and its function in the nervous system is still scarce, so that for the present we do not think it possible to discuss the assertions of Bogoch and put forth a hypothesis interpreting the findings we have here reported. The diminution of these substances in the CSF of oligophrenics and schizophrenics is in any case a basis for maintaining that in these patients there exists an altered metabolism of the glycolipides of the nervous system.

² Bogoch affirms, moreover, that he has met with an NA diminution in subjects affected by various neurologic diseases(5); in our researches we have obtained low NA values in some patients affected with multiple sclerosis, paralytic dementia, serious hemispheric atrophy due to carotid thrombosis. We have carried out determinations too in 4 cases of presenile, 3 of senile and 4 of atherosclerotic dementia, obtaining low values in the first two groups, normal values in the third; in consideration of the limited number of cases examined, these findings must however have further confirmation.

TRANLYCYPROMINE (PARNATE) A NEW MONOAMINE OXIDASE INHIBITOR

FREDERICK LEMERE, M.D.¹

In my experience, the most effective drugs available for the treatment of depression have been the monoamine oxidase inhibitors (Marsilid, Catron, Nardil, Niamid and Marplan). Even at best, however, their therapeutic efficiency leaves much to be desired. At the recommended safe dosage, they are often ineffective or so delayed in their results that patient and doctor become discouraged and electroshock may have to be resorted to. The search for an improved anti-depression drug therefore continues.

The drug used in this preliminary clinical screening trial was tranlycypromine (Parnate).² Tranlycypromine is a monoamine oxidase inhibitor that was dispensed in 10 mg. tablets. It was used either alone or in a tablet (Parstelin) combining it with 1 mg. trifluoperazine (Stelazine). In all, 39 private psychiatric patients were tried on this medication. Of these, 32 were predominantly cases of depression while the remaining 7 were mild schizophrenics with depression, apathy, exhaustion or withdrawal. The initial dosage was one 10 mg. tablet twice a day but this was raised to three a day or lowered to one a day depending on the reaction of the patient.

The evaluation of the results of drug therapy in psychiatric cases is always difficult, especially in depression which is usually a self-limiting illness anyway. I would like, therefore, to report only my prelimi-

nary clinical impression regarding this drug after using it in private practice for 6 months. Tranlycypromine compares very favorably with the other monoamine oxidase inhibitors as far as clinical improvement goes, with as good or better results. Many patients who had been on other monoamine oxidase inhibitors preferred tranlycypromine because it seemed to be more quickly effective, produced fewer side effects and usually needed to be taken only once or twice a day. The main advantage from the physician's standpoint is the relative rapidity of its benefits and the quick cut-off of its action (within 1 to 3 days) if side effects develop. Patients who improved did so within a few days to a week or two. Side effects were minimal and consisted of rare instances of insomnia, a feeling of overstimulation, a dizzy or fuzzy feeling in the head, dry mouth or sweating which subsided within a day or two after temporarily discontinuing or reducing the dosage of the drug. No cases of jaundice or serious hypertension were encountered in this group of patients.

CONCLUSIONS

Preliminary clinical experience indicates that tranlycypromine (Parnate) is an improved type of monoamine oxidase inhibitor that appears to be more rapid in its action, effective in smaller doses (1 to 3 tablets a day—usually one tablet b.i.d.) and relatively free of side effects. It is indicated for treatment of any type of depression and sometimes for withdrawn schizophrenic patients.

¹ From the Department of Psychiatry, University of Washington, School of Medicine, Seattle, Washington.

² The tranlycypromine (Parnate) used in this investigation was kindly furnished by the Smith Kline & French Laboratories.

CASE REPORTS

TREATMENT IN TRANSVESTISM

VERONICA M. PENNINGTON, M.D.¹

Transvestism is deviant sexuality in cases of sociopathic personality disturbance, characterized by cross-dressing.

Since earliest times it has been recognized that changing brain chemistry produces altered behavior; the treatment of our transvestite was carried on with that thought in mind.

Our patient's present illness began at the age of 6 when he first remembers fantasies of his intense desire to be a girl. He would sit apart from other children enjoying this fantasy, put on his sister's panties and masturbate. At the age of 9, he took the clothing of a neighboring woman from the line, retired behind a hill, masturbated, and returned the clothing to the proper place. The intense feelings of wishing to be a woman continued in spite of alcoholic excesses from the age of 16 through his 4 years of Army service and later. A month after his marriage, at the age of 23, he put on his wife's panties and came out before her. He always took the succubus position, and in the evening after their two children, girls, were in bed, he would go into his wife's bedroom, put on her clothing, using rouge and lipstick, and admire himself in the mirror, producing sexual gratification by masturbation. These episodes of cross-dressing increased, and he began to have suicidal ideation because his marriage and work seemed headed for disaster. After 7 years of marriage this 31-year-old television technician was admitted to this hospital on January 5, 1960. He had two acute periods of anxiety, one just prior to coming to the hospital in which he cross-dressed, went into a trance-like condition, partial shock, with profuse cold perspiration, trembling, and a period of amnesia for about a half an hour. When he awakened he felt complete satisfaction. Three days after admis-

sion to this hospital, when he had a strong desire to cross-dress, he had another anxiety reaction without loss of consciousness.

He was begun on nialamide, 50 milligrams q.i.d., meprobamate, 400 milligrams t.i.d., and chlorpromazine, 50 milligrams q.i.d. At first he continued to request that the conversion operation be performed on him. Five times he has considered mutilating himself by removing his external genitalia with a knife so that he could "truly be a woman." Cells from the buccal cavity were examined and XY male chromosomes were easily distinguishable and identifiable.

He had noticed 'cycles consisting of a feeling or a desire to be a woman, together with cramp-like abdominal sensations and the feeling that he had ovaries. He considered these to be menstrual symptoms. He thought many times of suicide and had four guns with which to accomplish this, but he made no actual attempt to do so.

He gradually improved, first in his sleeping and in fewer anxiety reactions, and his transvestitic tendencies gradually disappeared. Psychological testing before and after treatment corroborated his return to normal.

He was discharged as normal on February 5, 1960 and has resumed his former work. He has returned twice for personal interview in addition to writing about his progress. He continues to take the medication prescribed when he came to the hospital. He and his wife are happier than they have been since their marriage. His desire to be a woman now "seems like a bad dream."

CONCLUSIONS

1. Female psychosexual functioning in a male brain produced by some biochemical malfunctioning in the center of bisexual development antagonistic to the gender represented by the gonads may be the cause of transvestism.
2. Transvestism is perverted behavior which has been corrected

¹ 2010 East Meadowbrook Road, Jackson, Miss. From the Department of Psychiatry, University of Mississippi School of Medicine and the VA Center, Jackson, Miss.

chemically by the phrenotropic agents m-alamide, chlorpromazine, and meprobamate in a patient whose case was presented, resulting in complete negation of transvestitic symptoms and a return to normal behavior.

HISTORICAL NOTES

VETERA ET NOVA

If I were required to guess offhand . . . what is the bottom cause of the amazing material and intellectual advancement of the last 50 years [*i.e.*, the 2nd half of the 19th century], I should guess that it was the modern-born and previously nonexistent disposition . . . to believe that a new idea can have value. With the long roll of the mighty names of history present in our minds, we are not privileged to doubt that for the last 20 or 30 centuries every conspicuous civilization . . . has produced intellects able to invent and create the things which make our day a wonder; perhaps we may be justified in inferring, then, that the reason they did not do it was the public reverence for old ideas and hostility to new ones always stood in their way . . . the prevailing tone of old books regarding new ideas is one of suspicion and uneasiness at times, and at other times contempt. By contrast, our day is indifferent to old ideas, and even considers that this age makes their value questionable, but jumps at a new idea with enthusiasm and high hope . . . I make no guess as to just when this disposition was born to us, but it certainly is ours, was not possessed by any century before us . . . and is doubtless the bottom reason why we are a race of lightning-shod Mercuries, and proud of it—instead of being, like our ancestors, a race of plodding crabs, and proud of that.

. . . Nothing is today as it was when I

was an urchin; but when I was an urchin, nothing was much different from what it had always been in this world. Take a single detail, for example—medicine. Galen could have come into my sick-room at any time during my first 7 years [*i.e.*, 1835-1842] . . . and he could have . . . stood my doctor's watch without asking a question. He would have smelt around among the wilderness of cups and bottles and phials on the table . . . and missed not a stench that used to glad him 2000 years before, nor discovered one that was of a later date. He would have examined me and run across only one disappointment—I was already salivated; I would have him there; for I was always salivated, calomel was so cheap. He would get out his lancet then; but I would have him again; our family doctor didn't allow blood to accumulate in the system. However he could freight me up with old familiar doses that had come down from Adam to his time and mine . . . and if our reverend doctor came and found him there, he would be dumb with awe . . . Whereas if Galen should appear among us today . . . he would be told he was a back number, and it would surprise him to see that that fact counted against him, instead of in his favor. He wouldn't know our medicines; he wouldn't know our practice; and the first time he tried to introduce his own, we would hang him.

—Mark Twain

PROCEEDINGS OF THE AMERICAN PSYCHIATRIC ASSOCIATION

THE ONE HUNDRED AND SIXTEENTH ANNUAL MEETING, ATLANTIC CITY, NEW JERSEY, 1960

The 116th Annual Meeting of the American Psychiatric Association was held in Atlantic City, New Jersey, May 9-13, 1960, with headquarters at the Traymore Hotel. Business meetings and scientific sessions were held in Convention Hall.

The total registration was 5,077, making this one of the largest Annual Meetings, although smaller than the 1959 Annual Meeting by 27 persons. The registration included 2,434 members, 1334 guests, 393 exhibitors, 874 wives of members and 42 press representatives. Foreign guests included psychiatrists from Africa, Australia, England, Haiti, Italy, Japan, Poland, Portugal, Switzerland, and Turkey. The Program included 152 scientific papers and 19 Round Tables.

The opening meeting was called to order by Dr. William Malamud, President, at 9:30 a.m., on May 9. The Reverend William F. Doyle of Atlantic City delivered the invocation. The Honorable Robert B. Meyner, Governor of New Jersey, gave a welcoming address to the members, followed by the introduction of Dr. R. H. Felix, President-Elect, by Dr. Malamud.

Dr. Mathew Ross, Medical Director, was called upon to give his report to the membership. He spoke of the image of the administrative staff offices, noting the major mission essentially is one that entails communications—the receiving, storing, retrieving, processing, production, facilitating, and disseminating of communications. Reports were presented by Dr. Alfred Auerback, Speaker of the Assembly; Dr. Robert S. Garber, Chairman of the Arrangements Committee; and Dr. John Donnelly, Chairman of the Program Committee. Dr. C. H. Hardin Branch, Secretary, reported that the official membership count on March 31, 1960 was 11,037. Upon recommendation by the Council, three new District Branches were approved by the membership: Mid-

Hudson (N. Y.), Nebraska-North Dakota-South Dakota, and Ontario. This brings to 52 the number of District Branches in the Assembly. The Treasurer, Dr. Addison M. Duval, then reported that the Association had just completed a reasonably successful year financially and that the over-all financial condition had improved.

The Chairman of the Hofheimer Prize Board, Dr. David Hamburg, announced that the Association's \$1,500 prize was presented this year to Albert J. Stunkard, M.D., Associate Professor of Psychiatry at the University of Pennsylvania, for his work on obesity. The 1960 recipient of the Isaac Ray Award was Judge David L. Bazelon of the U. S. Court of Appeals in Washington, D. C. Dr. Ross announced the Somerset (Pennsylvania) State Hospital as the winner of the 1959 Mental Hospital Service Achievement Award. Honorable mention was also accorded to the Philadelphia (Pennsylvania) State Hospital and the Eastern (Oklahoma) State Hospital.

Dr. Felix then introduced Dr. Malamud, who presented his Presidential Address entitled "Psychiatric Research; Setting and Motivation." Dr. Felix was respondent. Dr. Malamud's Presidential address delineated "milestones of progress" in the recent history of the Association and elaborated on the role it might play in the future of psychiatric research by bringing its influence to bear towards providing more adequate settings and fostering appropriate motivation. He noted in closing that the nature of motivation in clinical investigation finds its highest expression in Schweitzer's principle of "Reverence for Life," and that "the fostering of this principle and the establishment of a setting in which it can be most effectively implemented could be regarded as a fundamental objective of our Association." Immediately following this address, the session observed a moment of

silence in memory of those members of the Association who had died since the 1959 Annual Meeting. The opening exercises were closed with a benediction by Rabbi B. Rubin Weilerstein.

The second business session was called to order by Dr. Malamud on Tuesday, May 10, at 2:00 p.m. The first item of business was a report of the results of the election of officers for 1960-61. The successful candidates were announced by Dr. Evelyn Ivey, Chairman of the Board of Tellers, as follows: Dr. Walter B. Barton, President-Elect; Dr. D. Griffith McKerracher, Vice-President; Dr. Raymond W. Waggoner, Vice President; Dr. C. H. Hardin Branch, Secretary; Dr. Addison M. Duval, Treasurer; incoming Councillors, Dr. Daniel Blain, Dr. David A. Boyd, Jr., and Dr. M. Ralph Kaufman.

Reports were presented by the Coordinating Committee Chairman reviewing the activities of their respective groups of committees during the past year and plans for the future. Dr. Harvey J. Tomkins, Chairman, reported for the Coordinating Committee on Technical Aspects of Psychiatry; Dr. Wilfred Bloomberg reported as Chairman of the Coordinating Committee on Professional Standards; and Dr. Paul Lemkau reported as Chairman of the Coordinating Committee on Community Aspects of Psychiatry. Dr. Branch, Secretary, then announced approval of Proposal No. 1 to amend Article III, Section 3, of the Constitution, Proposal No. 2 to amend Article V of the By-Laws. Proposal No. 3 offered as a substitute for a portion of Proposal No. 2 was defeated.

Following the completion of the business meeting and a brief recess, Dr. Malamud at 3:00 p.m. presided over the annual Convocation for newly elected Fellows. A total of 162 new Fellows attended the ceremony. Highlight of the Convocation was the Fellowship Lecture presented by Leo W. Simmons, Ph.D., of Columbia University on "A Sociologist's Views on Patient Care and Treatment." The ceremony was concluded with a recessional march.

The next business session was opened at 9:15 a.m. on Wednesday morning, May 11, by Dr. Malamud. Dr. Branch presented the report of the Secretary to the membership,

reviewing the actions of the Council since the last Annual Meeting. On motion duly seconded from the floor, these matters were approved by the membership. By separate motions the proposed new District Branches, the Mid-Hudson (N. Y.), the Nebraska-North Dakota-South Dakota, and the Ontario District Branch were approved by the membership. The membership also approved Chicago as the site for the 1961 Annual Meeting. Dr. Malamud then read the names of Officers, Councillors, and Committee Chairman retiring from office at this Annual Meeting and announced that each would receive a Certificate in recognition of his service to the Association.

The Annual Dinner was held on Wednesday evening at 7:30 p.m. in the American Room of the Traymore Hotel and was followed by light entertainment and dancing. Highlight of the evening was the presentation of a handsome scroll to Dr. Mesrop A. Tarumianz for his leadership in establishing the Central Inspection Board in 1948, and for his service as its Chairman since that time. The presentation was made by Dr. Felix and was acknowledged by the audience with prolonged applause. Dr. Malamud introduced various APA officials and their wives, as well as foreign guests.

The Adolf Meyer Memorial Lecture, another highlight of the meeting, was presented at 10:00 a.m. Thursday, May 12. Sir Aubrey Lewis, M.D., F.R.C.P., of London, England, spoke on "The Study of Defect."

The final business session was held on Friday morning, May 13 at 11:30 a.m. At this time, the actions taken by the Council on May 12 were reported by the Secretary, Dr. Branch. The report was accepted by the membership upon motion from the floor. Dr. Malamud presented Certificates to those who were retiring from office and indicated his appreciation to the membership and staff for their assistance and cooperation during his tenure as President.

With the presentation of the gavel, Dr. R. H. Felix was formally installed as President of the Association for the coming year, and he announced the new Officers for the Assembly of District Branches: Dr. John R. Saunders, Speaker; Dr. Edward Billings, Speaker-Elect; Dr. Lester Shapiro,

Recorder; Dr. Alfred Auerback, Past Speaker; and Dr. Walter H. Obenauf, Parliamentarian. Area members of the Policy Committee are Dr. Robert S. Garber, Northeast, Dr. William L. Holt, New York, Dr. Hamilton Ford, South, Dr. G. Wilse Robin-

son, Jr., Midwest, and Dr. G. Creswell Burns, West.

After a few brief remarks by the new President, this final session was adjourned and the 116th Annual Meeting was officially closed at 5:00 p.m. on May 13, 1960.

SUMMARY OF MEETINGS OF COUNCIL AND EXECUTIVE COMMITTEE, MAY 1959 TO MAY 1960

This report presents, in summary form, the principal actions of the Council and the Executive committee at meetings held throughout the year. Many routine matters, such as referrals to Committees prior to definitive actions, are not included. Copies of the full minutes have been forwarded to the officers of each District Branch and Affiliate Society following the various meetings to keep their members informed of the matters considered and the actions that resulted.

Executive Committee Meetings, June 27 and September 17, 1959. Directed that the explanatory material regarding alternate proposed amendments to Article V, Section 2 of the By-Laws be included with the ballots. Approved a joint meeting between the Section on Psychotherapy and the Academy of Psychoanalysis in accordance with the rules and practices of the Association. Approved the Resolutions of the Exploratory Conference on Standards of Psychiatric Hospitals regarding present hospital standards and the principles underlying them. (The following three Resolutions were subsequently approved by the Council on November 13-14, 1959.) BE IT RESOLVED (1) That the present standards for public mental hospitals have been and continue to be indispensable for improving patient care; (2) That the Committee on Standards initiate a long-term basic study of hospital programs from the standpoint of existing practices and changing trends to determine whether there is need to modify present standards and the directions such modification should take; (3) That the Committee on Standards solicit sufficient funds from appropriate sources to carry out the above recommendations. Agreed that the furnishing of a patient's name, address

and diagnosis in governmental reports comes within the purview of ethical practice. Expressed interest in "Project Hope" and suggested that the project might be endorsed later when its program is developed more fully. Expressed approval of the plan for APA-endorsed magazine articles on psychiatry and directed the Medical Director to proceed with the necessary negotiations. Requested that psychiatrists continue to be listed with biological scientists in the publication *American Men of Science*. Authorized the Medical Director and Dr. Alfred Auerback to investigate the possibility of holding a meeting in Tokyo, Japan, following the 1963 Annual Meeting. Authorized the Medical Director to handle at his discretion the matter of APA participation in a Joint Eastern Management Symposium. Accepted the report of the Speaker of the Assembly who noted that he planned to devote considerable time to working with the communications problem. Decided that the selection of Divisional Meeting papers for publication should be made locally by a publication committee which would function entirely independent of the Divisional Meeting program committee. Suggested that the Assembly review the problem of publishing Divisional Meeting papers and submit recommendations to the Council. Directed that as of June 15, 1959 no further commitments of Manpower Project funds should be made, pending further study of the matter by the Ad Hoc Committee on the Manpower Project and the Medical Director. Authorized Dr. William Malamud to represent the Association on an advisory group to assist in the evaluation of American Medical Association scientific activities. Authorized the transfer of the 1962 Annual Meeting from Montreal to Toronto, Canada.

Authorized the employment of part-time secretarial help in the office of the Program Committee Chairman and increased the budget for the Committee to \$3,500 for the 1959-60 fiscal year. Directed the Program Committee to make the following changes for the 1960 Annual Meeting: Shift the Friday business meeting from 9:30 a.m. to later that forenoon, schedule as many significant papers as possible for the Friday morning session, and have the Friday business meeting listed in the printed program with capitalization to emphasize the importance of the session. Directed the Speaker of the Assembly and the Program Committee Chairman to contact the District Branches and solicit their comments and recommendations regarding all aspects of Annual Meeting Sections. Extended to Dr. Mathew Ross a vote of commendation for his work with the "Statement of Principles for Planning Facilities and Services for Psychiatric Care" and authorized him to continue negotiations with the American Hospital Association. Requested the Committee on Liaison with the AHA to contact the Committee on Standards and Policies of Hospitals and Clinics regarding the preparation of a report on psychiatric services in general hospitals. Complimented Mr. Austin Davies for his effective action in bringing attention to the proposed separate listing of psychotherapists in the New York City telephone directory and assisting in effecting a satisfactory conclusion. Agreed that a simple explanation by the Speaker of the Assembly should be published in the January 1961 issue of the *American Journal of Psychiatry* with the explanation by the Committee on Constitution and By-Laws regarding the alternate choices for the proposed amendment to Article V, Section 2 of the By-Laws (District Branch membership). Directed the House Committee to consult with the Medical Director regarding the responsibility of the Committee in the operation of the Central Office building. Authorized the Medical Director to seek funds to finance a conference on aging in accordance with his proposal. Directed the House Committee and the Medical Director to review the proposal to purchase additional properties adjacent to the Central Office and present a recom-

mendation to the Council. Accepted the results of mail ballot among the Council regarding the proposal to schedule Council and fall Committee Meetings several years in advance.

Council Meeting, November 13-14, 1959. Approved the minutes for the Council Meetings of April 25-26 and 30, 1959 as amended. Ratified the actions of the Executive Committee on June 27 and September 17, 1959. Welcomed Dr. C. H. Hardin Branch, Secretary, following an illness of several months and acknowledged its indebtedness and appreciation to Dr. Lawrence C. Kolb who, as Acting Secretary in Dr. Branch's absence, carried the burden of the office so generously and performed the duties with such exemplary efficiency and dispatch, and discharged him with thanks. Directed the Treasurer to withhold payment of excess expenses of Committees or other organizational units of the Association when such amounts exceed the official budget approved by the Council. Directed the Executive Assistant to inform all organizational units of the amount of the budget for the fiscal year. Directed the Central Inspection Board to proceed to fulfill its present contractual agreements but not to develop any new agreements for inspection, or reinspection, and ratings of additional hospitals. Authorized an ad hoc Committee to study the CIB and prepare recommendations for the Council regarding further program planning. Deferred action on the proposed 1960-61 budget for the CIB and directed the Board to submit an accurate revised budget with consideration of the above actions. Directed that the Joint Information Service be continued until it is demonstrated that some other agency can adequately replace its purposes. Directed the Budget Committee to consider revisions to the present budgeting system which will reflect more clearly the work assignments of the staff. Increased the membership of the Budget Committee to seven with the addition of the Treasurer as a voting member of the Committee by virtue of his office. Amended the proposed budget for 1960-61 by increasing the amount allotted to the Nominating Committee to \$2,000 and decreasing the amount allotted to the Commission on Principles and Position on Cur-

rent Issues in Psychiatry to \$6,000. Directed that the funds for the Committee on Certification of Mental Hospital Administrators be budgeted and audited on the same basis as other Association funds. Approved, as amended, the 1960-61 budget as recommended by the Committee on Budget with the exception of items of income and expenditure for the CIB. Directed that the Dr. Agnes McGavin Bequest be placed at the disposal of the Treasurer for action at his discretion, with the condition that these funds not be used for operating expenses of the Association and that the identity of the funds be maintained if at all possible. (This action was subsequently revoked when it was learned that a restrictive clause limited the expenditure of the bequest.) Received the report of the Medical Director which reviewed the highlights of recent developments in the Central Office and noted some personal observations and recommendations. Authorized an increase in the price of the Membership Directory from one to two dollars for members and from two to three dollars for non-members. Authorized an increase in the price of the *Summaries of Scientific Papers* from \$2.50 to \$3.00 and voted to continue the 25c charge for extra copies of the Annual Meeting Program. Agreed with the Commission on Long Term Policies suggestion that the present policy encouraging members to attend Council Meetings as individuals as well as official observers was sufficient. Approved in principle the recommendation of the Commission on Long Term Policies that a Conference on Post-Graduate Teaching in which state hospitals would be fully represented should be called at an early date. Discussed the 1961 World Congress of Psychiatry which will be held in Montreal. A special APA Committee consisting of Drs. Francis Braceland, Winfred Overholser and Lothar Kalinowsky will work with the Canadian Psychiatric Association and arrange post-congress tours of facilities in the United States. Considered favorably the suggestion of the Policy Committee that the membership approve the transfer of Washoe County, Nevada to the Intermountain District Branch. Approved Divisional Meetings in 1961 in Salt Lake City (Area V), Milwaukee (Area IV), and New York City

(Area II). Approved the recommendation of the Program Committee regarding Post-Graduate Teaching Sessions at the Annual Meeting with the proviso that there be only one such session at each meeting, that it be financed by Association funds with expenses limited to \$200, that there be no charge for tickets, and that tickets be available to members only, on request, on a first-come, first-served basis. Directed the Secretary to write to the various organizations that meet immediately before the Annual Meeting asking them to consider the possibility of rescheduling their respective meetings immediately after the Annual Meeting. Authorized the Program Committee to schedule the final business meeting at 11:30 Friday morning, with all scientific sessions scheduled to terminate prior to that time. Directed that any royalties received by the Association for the sale of scientific papers from the Honolulu Divisional Meeting should be placed in the special book fund for the Central Office Library. Approved the recommendations of the Committee on Committees regarding the House Committee as follows: That the Committee be limited to seven members, that the tenure of appointment for new members be seven years, that in making new appointments the President consider the availability of the immediate past-president of the Washington (D. C.) Psychiatric Society, and that a rotation schedule should become effective in 1960 with the oldest member in point of service on the Committee retiring first, the next oldest retiring in 1961, etc. Approved the recommendation of the Committee on Committees that a Committee on Juvenile Delinquency not be established and that the Committee on Child Psychiatry be given specific responsibility for working in the area of juvenile delinquency in cooperation with other interested Committees. (The name of the Committee on Child Psychiatry was later changed to Committee on Psychiatry of Childhood and Adolescence.) Directed the Central Office to send out available information on the problem of the aging as it relates to the White House Conference to the Directors of the respective state mental health programs with the suggestion that this material be brought personally to the attention of the Governor of

each state. Authorized employment of a Librarian for the Central Office to facilitate the development of a Library illustrating the history of American psychiatry, provided this can be accomplished within the provisions of the 1960-61 budget. Authorized the appointment of a Steering Committee to develop tentative plans for a conference on the responsibilities, functions and training of psychiatrists, and authorized the Steering Committee to seek outside funds to support such a conference. Approved in principle the recommendation of the Committee on Mental Deficiency for an exploratory conference on mental deficiency and referred the matter back to the Committee for recommendations regarding implementation. Directed the Medical Director to communicate with the Chairman of the Council on Mental Health of the American Medical Association advising him of the recommendation made by the Committee on Public Health that residency programs should include provisions for appropriate training in community mental health program administration and that examination for certification in psychiatry by the American Board should include this subject; and to request the Council on Mental Health to consider this if they deem it appropriate. Restated its previous policy regarding a personal appearance before the Council by a Committee Chairman within the Coordinating Committee system, indicating that if a Chairman is of the opinion that his Coordinating Committee Chairman will not present a recommendation adequately, the two are in disagreement regarding a recommendation, or for any other reason the Chairman feels the interests of his Committee will be best served by his appearance before the Council, he has a right to request to be heard. Such requests will be addressed to the President with the Coordinating Committee Chairman fully informed. Approved the recommendation of the Committee on Nomenclature and Statistics and continued its membership at nine until May 1961. Approved the recommendation of the Committee on Psychiatric Nursing and reaffirmed its statement of policy dated November 5-6, 1955: "The APA considers that the training and development of psychiatric aides as technical

specialists within the nursing services of mental hospitals is most auspicious for the advancement of treatment and care of the mentally ill, but considers that the formulation of legislation to govern the qualifications, training standards and practices of psychiatric aides should be deferred until this area within the general field of nursing has been more fully defined." Approved the recommendation of the ad hoc Committee on the Manpower Project to utilize funds remaining in the Manpower Project account to employ an agent to set a design for the Project and to meet necessary expenses for constructing these plans for future action. Directed that the program already arranged by the Section on Psychotherapy be adhered to for the 1960 Annual Meeting and instructed the Commission on Long Term Policies to study the whole Section structure and present recommendations at the next Council Meeting. Approved the request of the Committee on Academic Education for authority to seek outside funds to subsidize publication of its bibliography of the scientific literature on youth covering the years 1945-58. Approved the request of the Committee on Cooperation with Leisure Time Agencies to change its name to Committee on Leisure Time and Its Uses. Approved in principle the recommendation of the Committee on International Relations that the APA offer its assistance to the State Department in the matter of exchange visits of United States and U.S.S.R. psychiatrists. Accepted the report of the Commission on Principles and Position on Current Issues in Psychiatry which noted that the position of Legislative Aide had not been filled because a suitable candidate had not been located. Drs. Francis Braceland and Jack Ewalt will continue to represent the Association before Congressional Committees. Requested the President to appoint three members of the Association knowledgeable in real estate matters to consult with the House Committee and present a recommendation regarding the wisdom of the proposal to purchase three row houses adjacent to the Central Office. Authorized the House Committee to obtain a six-month option on these properties for a sum not to exceed \$1,000 which could be applied later to the purchase

price if the decision is made to buy these properties. Approved the recommendation of the House Committee and authorized the purchase of rugs and drapes to complete the decoration of the second floor of the Central Office at a sum not to exceed \$2,000. Authorized the establishment of a special account at the Central Office with \$3,000 from grant funds of the SK&F Foundation Fellowships. This action was taken at the request of the SK&F Foundation Fellowship Committee to facilitate the mailing of checks and certificates to award winners. Directed that Dr. Charles Roberts be retired from the Joint Committee with the Canadian Psychiatric Association and suggested that this liaison committee consist of two representatives from each association. Accepted greetings from the Mexican Psychiatric Association and the Mexican Psychoanalytic Association extended by Dr. S. Spafford Ackerly, Vice-President, who visited Mexico City representing the APA. Directed that when an Officer represents the Association at an outside meeting, his expenses shall be reimbursed either by the society extending the invitation or by the APA from the Council Contingency Fund.

Executive Committee Meetings, January 5, February 20 and March 26, 1960. Advised by the Parliamentarian that the establishment of Chapters as geographical subdivisions of District Branches would be in conformity with the APA Constitution and By-Laws, the Executive Committee directed that the policy of the Association shall be that there is no interdiction against the establishment of geographical sub-divisions, which may be called "Chapters," within District Branches at their discretion, with the proviso that these sub-divisions shall have no official status nor recognition by the Association. There will be only one official representative from each District Branch to the Assembly or other official functions where a District Branch is represented. Accepted the report of the Committee on Relations with Psychology and authorized its publication in the *American Journal of Psychiatry* at an early date. Approved the recommendation of the Committee on Relations with Psychology and increased the size of the Committee to seven members to coincide with its counterpart Committee

from the American Psychological Association for a period of three years effective at the 1960 Annual Meeting. Approved the recommendation of the Committee on Liaison with the American Academy of General Practice that the Committee be authorized to cooperate and consult with the Wyeth Laboratories in the production of film considered useful in orienting general practitioners to psychiatric subject matter providing (1) that the role of the APA ad hoc Committee be confined to that of providing consultation and that if any credit lines appear in the film they shall not indicate or imply more than that; (2) that the final version of the film shall have the full approval not only of the consultants of the Committee on Liaison with AAGP but also of the Association's Committee on Public Information and the Public Information Officer; (3) that the film shall not contain any advertising of a specific drug product; (4) that this action shall not be taken as implying approval of future requests for such collaborative effort with private firms but rather that each such request shall be considered on its own merits; (5) that this action shall not involve any expense to the Association. Directed the Treasurer to work out the problem of deficit financing remaining in the budget in collaboration with the Executive Assistant and the Medical Director. Authorized Dr. William Terhune to write to each member with an outstanding pledge, to the Building Fund requesting payment. Appointed Dr. Henry Laughlin to represent the APA on the Permanent Council of the Institute for the Advancement of Medical Communication for one year. Appointed Dr. Leonard Duhl to represent the Association at the International Conference on Mental Deficiency in England. Appointed Dr. D. Ewen Cameron to represent the Association at the meeting of the Latin-American Psychiatric Association in Havana. Was informed by the President that he had appointed Drs. Robert S. Garber, Robert Hewitt and Paul Lemkau to consult with members of the House Committee regarding the proposal to purchase three properties contiguous to the Central Office. Was informed that Dr. George S. Stevenson had received for the Association the Dr. Agnes McGavin Bequest totalling

\$22,023.38. Since the terms of the will stipulated that the bequest must be used for some aspect of child psychiatry, the matter was referred to the Committee on Psychiatry of Childhood and Adolescence. Reaffirmed its interest in the matter of exchange visits of U.S.S.R. and U. S. psychiatrists and referred the matter back to the Committee on International Relations for the formulation of specific recommendations to implement the proposal, including the problem of financing the exchange visits. Directed that when an individual is appointed to serve as an official representative of the APA, he should be requested to submit a written report of all matters that he considers of importance in connection with the meeting. This report is to be sent to the Medical Director for reproduction and distribution to the Council and appropriate APA Committees. Was informed of the Presidential appointment of Dr. Alfred Auerback to represent the Association at the Pan-American Medical Conference in Mexico City. Approved the report and recommendations presented by the Special ad hoc Committee to Program the Future of the Central Inspection Board. The essential recommendations were that the CIB be terminated on December 31, 1960, that a reconstituted consultation service be set up within the Mental Hospital Service limited to one consultant and one secretary with possible staff expansion later if necessary, and that the consultant's reports be reviewed by the Mental Hospital Service Board of Consultants. Instructed the Medical Director to implement the recommendations and emphasized that the consultative functions of the CIB will be taken over by the MHS. Directed the Secretary to notify the President of the Board of the National Association for Mental Health of the termination of the CIB and to request that NAMH consider favorably the possibility of providing continued financial support for the consultative functions of the CIB under the jurisdiction of the MHS. Suggested that the President send a letter to Dr. Mesrop A. Tarumian, Chairman of the Central Inspection Board, expressing the appreciation of the Association to him and the members of the CIB for their excellent work over the years. Authorized a supplemental

appropriation of \$300 to the 1959-60 budget of the Coordinating Committee on Technical Aspects of Psychiatry. Authorized a supplemental appropriation of \$800 to the 1959-60 budget of the Coordinating Committee on Professional Standards. Appointed a Special Committee comprised of the Medical Director, the Public Information Officer, the Executive Assistant and one member from both the 1960 and 1961 Arrangements Committees to study material compiled by the 1960 Arrangements Committee regarding pre-registration by mail for the Annual Meeting. The two immediate Past-Chairmen of the Arrangements Committee (1958 and 1959) were named as consultants to the Committee. Authorized the Committee on Grants and Awards to continue negotiations with the Geigy Pharmaceutical Company for the establishment of an APA travel fellowship and to conclude the negotiations at its discretion if the proposal is amended to agree with the APA regulations governing such matters and to permit American psychiatrists to visit Europe on the same basis that European psychiatrists would visit the U. S. Accepted the resignation of Dr. Dick McCool as Chairman of the Membership Committee because of illness but retained him on the Committee until his normal retirement. Approved the appointment of Dr. Mary Jackson as Chairman of the Membership Committee for the remainder of the 1959-60 Presidential Year. Reappointed Dr. Benjamin Simon to represent the Association to the American Occupational Therapy Association Medical Advisory Council. In accordance with the recommendation of the Committee on Committees did not approve a request for Standing Committee status from the ad hoc Committee on Education in Public Hospitals in Liaison with the American Psychoanalytic Association on the grounds that other Committees, singly or in unison, can handle the work undertaken by this ad hoc Committee. Also in accordance with the recommendation of the Committee on Committees did not approve a request from the Committee in Liaison with the American Academy of General Practice to increase its membership to nine. Dr. Zigmond Lebensohn, Chairman of the House Committee, reported that in accordance

with the directive of the Committee, he contacted the members of the Executive Committee by telephone and telegraph and received permission to use the entire \$1,000 authorized by the Council as an option on one of the row houses contiguous to the Central Office. In accordance with the recommendation of the House Committee, the Executive Committee authorized an amount not to exceed \$2,000 to be made available to the House Committee for the purpose of completing its original assignment by securing options on one or both of the two parcels of property 1807 and 1811 R Street, if and when they become available during this coming year. Suggested that the Speaker of the Assembly should review the matter of registration fees at Divisional Meetings for invited guests who are non-members of APA. Was informed by the Medical Director that the following dates were selected by mail vote of the Council for the fall Committee and Council Meetings for the period 1960-63: Committees: October 28-29, 1960, November 3-4, 1961, October 26-27, 1962, October 25-26, 1963; Council: December 2-3, 1960, November 24-25, 1961, November 23-24, 1962, November 22-23, 1963. Appointed two representatives to the White House Conference on Children and Youth, Mr. Robert L. Robinson of the Central Office as press representative and Dr. Alfred M. Freedman as alternative APA representative, in addition to the previous Presidential appointment of Dr. Reginald Lourie as APA representative. Selected Drs. Kenneth Appel and Bernard Alpers to represent the APA at the annual meeting of the American Academy of Political and Social Science. Was informed by the President-Elect of the appointment of a Steering Committee Co-Chaired by Dr. William Malamud and Dr. Walter Barton to develop tentative plans for a conference on the responsibilities, functions and training of psychiatrists as approved by the Council. Directed the Chairman of the Coordinating Committee on Community aspects of Psychiatry to contact the Committee on Nomenclature and Statistics regarding the problems of comparison between different systems of nomenclature and statistics which are no longer merely local or national, but fre-

quently international, in scope. Authorized the Speaker to insert in the Mail Pouch a statement summarizing what is going on in the Association as an effort to improve communications within the Association. Authorized the Association to join with the National Association for Mental Health and the World Federation for Mental Health in sponsoring, without cost to the APA, a program on mental health during the 8th World Congress on Rehabilitation which is scheduled in New York City in August 1960. Appointed Dr. Maurice Friend, Chairman of the Committee on Psychiatric Social Work, to represent the Association at the meeting of the Social Welfare Assembly, National Health Council on April 22, 1960. Appointed Dr. Lothar Kalinowsky, Chairman of the Committee on International Relations, to represent the Association at the meeting of the World Federation for Mental Health, United States Committee, on April 22, 1960. Authorized the Committee on Aging to proceed with the development of its exhibit on aging in accordance with its original proposal and recommended that space be provided for the exhibit at the 1960 Annual Meeting. Instructed the Medical Director to inform his correspondent that the Association approved in principle the proposed meeting of professors of psychiatry during the Annual Meeting, but suggested that a more satisfactory time for such a meeting would be the day following the fall Committee Meetings. Authorized publication of Round Table Proceedings with subsidization from pharmaceutical houses provided the acknowledgement of the drug firm does not exceed the statement published in Regional Research Report No. 12. ("The American Psychiatric Association gratefully acknowledges the assistance of the Schering Corporation in making publication.") Editorial supervision must be provided by the Round Table personnel, subject to the approval and release of the material by the Editorial Board of the Journal. Approved the revised budget of the Central Inspection Board which amounted to \$35,950 for the period April 1-December 31, 1960. Was informed that the National Association for Mental Health had authorized the continuance of their \$10,000 annual contribution to the CIB by

transferring the contribution to the proposed consultation service of the Mental Hospital Service on December 31, 1960. Agreed to underwrite the salaries for the Project Director and Secretary of the General Practitioner Education Project for a two-month termination notice period beyond June 30, 1960 in case the application for a renewal grant is not approved, and agreed to underwrite the Project expenses until the renewal check is received if the application is approved. In the latter instance, the grant period would be retroactive to July 1. Approved publication of a Biographical Directory every five years with no Membership Directory published in such years. A Membership Directory will be published in all other years. Rejected a proposal for APA participation in a television series. Approved the statement honoring Dr. Mesrop A. Tarumian for his work with the Central Inspection Board and directed Mr. Robert L. Robinson to have the statement reproduced in an appropriate fashion for presentation at the Annual Meeting. Appointed Dr. Henry Laughlin to represent the Association at the 1960 Royal Medico-Psychological Association Meeting.

Council Meeting, May 7-8 and 12, 1960. Approved the minutes for the Council Meeting of November 13-14, 1959. Ratified the actions of the Executive Committee on January 5, February 20 and March 26, 1960. Reiterated its previous action approving the procedure of borrowing funds from subsequent years' dues to pay for renovations to the Central Office building in lieu of establishing an expensive mortgage arrangement. Established an Internal Management Committee consisting of the President-Elect (Chairman), Treasurer, Chairman of the Budget Committee and the Medical Director, with the President acting as a consultant, to develop improved internal management of the Association including delineation of the authority and responsibility of Officers and staff members and to develop clearer objectives and improved financial methods including a written operations manual. Approved the request of the Membership Committee and granted a year's extension of its assignment to study all aspects of the membership requirements in the Association. Recommended acceptance by the

membership of the amended list of candidates for election to membership or change in status as submitted by the Membership Committee. Directed that the criteria for referral of patients to a psychiatrist are the same as for referral of patients to any medical specialist by a physician outside that specialty. Authorized the Medical Director to expend funds at his discretion for Library purchases from the special book fund. Authorized the solicitation of funds from available sources, including contributions from members, to finance the development of the Central Office Library. Appointed Dr. Kenneth Gray to replace Dr. Walter L. Treadway, resigned, on the Editorial Board of the Journal. Approved the recommendation of the Commission on Long Term Policies that the proposal for the establishment of a new membership classification not be accepted. Approved the recommendations of the Commission on Long Term Policies regarding Annual Meeting Sections as follows: (1) Abstracts of all papers, including those of the Sections, shall be submitted to the Program Committee by the established deadline. (2) The Program Committee shall rate the papers submitted by a Section for qualification on the program as is done with other papers. (3) If a Section fails to submit an adequate program by the established deadline, the Section forfeits the right to a Section meeting for that year. (4) If a Section fails for three successive years to provide an adequate program, the Program Committee will report this to the Council. (5) If a Section does not have adequate papers in number or quality, the Program Committee may place appropriate papers in that Section. Authorized the appointment of an ad hoc Committee to study the Convocation and report to the Council. Was informed that the Associated Clinical Psychiatrists' Prize has been officially discontinued by the donor. Directed that the formulation of awards and commendations be referred to the Committee on Grants and Awards for suggestions as to a uniform procedure and format. Approved the recommendation of the Committee on Constitution and By-Laws to disapprove a proposal to create two types of Honorary Fellows—scientific and philanthropic. Nominated Dr. Lawrence C. Kolb to the American

Board of Psychiatry and Neurology to replace Dr. William Malamud who retires from the Board in December 1960. Approved the revised budget for 1960-61 as recommended by the Treasurer and the Budget Committee with income projected at \$803,082 and expenses projected at \$775,606. Approved the employment of Dr. Bartholomew W. Hogan as a member of the Central Office staff. Directed that the remaining uncommitted funds of the Manpower Project should be used for the purpose of coding on electronic data processing cards, membership information available in the Central Office and that this operation should be considered a portion of the overall study of psychiatric manpower. Discharged the ad hoc Committee on Manpower with thanks. Referred to the Commission on Long Term Policies the suggestions presented by petition from members of the Section on Psychotherapy to revise Section business meeting procedures, i.e., registration, voting procedures and representation, and directed that an appropriate report and recommendations should be presented for consideration by the Council. Received an information report stating that it appeared unlikely that exchange visits could be developed in the near future between U.S.S.R. and U. S. psychiatrists. Received the report of a Central Office study of foreign-trained physicians in U. S. mental hospitals occasioned by the A.M.A. Council on Medical Education and Hospitals requirement that effective July 1, 1960 all such graduates must be certified or fully licensed to serve as interns or residents in U. S. hospitals. Hospitals not meeting this requirement will have their training programs disapproved. The study indicated that 10% of the physicians employed in institutions with psychiatric residency training programs are vulnerable. These include 143 residents and 568 staff physicians—80% in state hospitals, 11% in state schools, 6% in private hospitals, and 3% miscellaneous. Directed the Central Office, in collaboration with the Ohio District Branch, to obtain as much information as possible on methods being used in the various states and provinces to meet the problem of reimbursement for patient care in public institutions. Approved the recommendations of the House

Committee that : (1) The property numbered 1809 R Street be purchased for \$25,000, financed by the sale of securities ; (2) that properties 1807 and 1811 R Street be purchased as soon as they can be acquired satisfactorily in the judgment of the Committee utilizing funds already authorized for options to remove them from the market until financial arrangements for their purchase can be completed ; and (3) that all such purchases be effected in a straw name until all properties are acquired. This negotiation amounts to a transfer of investments from securities to real estate. Was informed that the proceedings of Annual Meeting Round Tables are the property of the APA and that their publication in any manner is subject to the release of the material by the Editorial Board. Indicated that the Association will not make a policy statement on the matter of planned parenthood and/or birth control. Elected Dr. Robert H. Felix as Moderator for the Council. Elected Drs. William Malamud and Aldwyn Stokes to serve on the Executive Committee. Approved the request to have a Divisional Meeting in Washington, D. C. in the fall of 1962. Approved three new District Branches : Mid-Hudson (N. Y.), Nebraska-North Dakota-South Dakota, and Ontario. Approved the recommendation of the ad hoc Committee to Review Expenses and Speaking Engagements of Vice-Presidents that if a Vice-President travels as an official representative of the President and the District Branch or other organization acting as host does not pay for actual and necessary expenses in conjunction with the trip, he shall be remunerated from the Contingency Fund of the Council. Authorized the Committee on Psychiatry of Childhood and Adolescence to sponsor jointly with the American Academy of Child Psychiatry a conference on the training of the child psychiatrist with funds for the conference to be secured from a source independent of the APA. Approved the recommendations of the Committee on Public Health to reconstitute the Contract Survey operation of the Central Office and authorized the President to appoint a Board to (a) determine whether a survey should be done, (b) determine the method of doing the survey, (c) review the report before its release and

(d) act in accordance with specific authority of the Council in supervising the work of the staff in this area of activity. Authorized the Medical Director and the Committee on Psychiatric Nursing to explore further the possibility of scheduling a multidisciplinary conference on means of improving total patient care, with particular emphasis on inservice education. Went on record as officially opposing any mandatory suspension of the medical license or right to practice when a physician becomes mentally ill or emotionally disturbed. Approved the recommendation of the Committee on National Defense that the APA is not in a position to comment on the selection or use of any particular type of military weapon. This recommendation resulted from a communication received from a member of the House of Representatives regarding the use of biological and chemical warfare. Authorized the Chairman of the SK&F Foundation Fellowship Committee to explore informally and to receive an additional grant if it is offered to continue the work of the Committee. Authorized the announcement of the winner of the George N. Raines Award at the Annual Meeting. Approved the recommendation of the Mental Hospital Service Board of Consultants that the consultation service which will succeed the Central Inspection Board under the MHS also undertake the inspection of hospitals/schools for the retarded according to the standards promulgated by the Committee on Standards and Policies of Hospitals and Clinics for the purpose of rating such institutions. Approved the recommendation of the MHS Board of Consultants that a Sub-Committee of five members of the Board who have had experience in inspection and rating hospitals and schools be appointed to rate the hospitals/schools for the retarded which are inspected, and that they be authorized to issue certificates to fully approved institutions using the rating system previously approved by Council for use by the CIB. Approved the recommendation of the MHS Board of Consultants that a separate Sub-Committee of the Board, consisting of three members, be appointed to review the reports and recommendations made by the MHS consultants following

surveys and consultations regarding other types of institutions. Heard the Incoming President announce the appointment of Dr. Howard P. Rome as Chairman of the Coordinating Committee on Professional Standards replacing Dr. Wilfred Bloomberg. Approved the appointment of Dr. Dick McCool as Chairman, and Dr. A. E. Davidson and Dr. Marvin L. Adland as new members of the Membership Committee. Approved a change of name to the ad hoc Committee on Recognition for Allied Service Personnel in Mental Hospitals (formerly the ad hoc Committee on an Organization for Mental Hospital Personnel). Continued the following ad hoc Committees: Insurance, Joint Committee with the Canadian Psychiatric Association, District Branch Committees, and Education in Public Hospitals in Liaison with the American Psychoanalytic Association. Instructed the Secretary to notify the Secretary-General of the Japanese Society of Psychiatry and Neurology that the Association is interested in visiting Japan and is exploring further the details regarding the proposed 1963 meeting in Tokyo. Approved the membership questionnaire as submitted by the Medical Director for the coding of membership information on IBM cards and authorized its implementation. Approved the plan presented by the Medical Director representing the ad hoc Committee on Pre-Registration to conduct a limited experiment in pre-registration for the 1961 Annual Meeting. Approved the recommendation of the Board of Tellers that future ballots require the voter to cast only one vote for the slate of Officers submitted by the Nominating Committee with the exception of Councilors who will continue to require individual votes to determine the successful candidates. Approved the recommendation of the Board of Tellers that when propositions are to be included on the ballot, its format will be prepared after consultation between the Chairman of the Board of Tellers and the Chairman of the Committee on Constitution and By-Laws. Noted the passing of Drs. George N. Raines, Gregory Zilboorg and Adolph Rehns, all of whom were serving as members of Committees or Boards at the time of their death.

REPORT OF COORDINATING CHAIRMAN, COORDINATING COMMITTEE ON THE TECHNICAL ASPECTS OF PSYCHIATRY

The year has been marked by intense committee activity operating in multiple significant areas. The committees have been sensitive to immediate needs as well as issues requiring long term planning and investigations. There has been a ready recognition of problems requiring joint action by individual committees together with the development of avenues of communication enabling the various committees, national and local, to become better acquainted with one another's ongoing activities.

More specifically, the Committee on Aging, under the chairmanship of Ewald Busse, M.D., has designed an exhibit on the psychiatric problems of the aged which is on view, for the first time, at this meeting. It is hoped that this exhibit will be used elsewhere and particularly at the 1961 White House Conference on Aging. The project has been the immediate responsibility of a member of the committee, Maurice Linden, M.D. The cost of this display has been defrayed through outside funds. The Eleventh Mental Hospital Institute had as its main theme, the problems of aging. The committee assisted in the planning of this Institute and members actively participated in the Institute itself. The Institute provided the occasion for much constructive thinking—there was a greater clarification of issues involved—and added opportunities for sound planning. The committee is presently engaged in further preparations for the White House Conference. At the committee's request, Council directed the Central Office to send out available information on the problem of the aging as it relates to the White House Conference to the directors of the respective state mental health programs with the suggestion that this material be brought personally to the attention of the Governor of the state.

The Committee on Psychiatry of Childhood and Adolescence, formerly called the Committee on Child Psychiatry, under the chairmanship of Franklin Robinson, M.D., has been primarily involved in the recently instituted certification of Child Psychiatry as a subspecialty under the American Board of Psychiatry and Neurology. The implications of this action are presented in detail in Dr. Robinson's paper "Current Status of Child Psychiatry" published in the February 1960 issue of the *American Journal of Psychiatry* and these have received the attention of this committee throughout the year. The committee has

accepted the primary responsibility of investigating the general area of juvenile delinquency with the expectancy of coordinating their efforts with other interested committees.

J. Sanbourne Bockoven, M.D., chairman of the Committee on History reports the following activities: 1. The period of April 1959–November 1959 was largely devoted to acquiring background data regarding the possibilities of sponsoring a research project on the History of Contemporary American Psychiatry. Time, travel and correspondence were invested by committee members in the interests of acquiring books of historical value for the library at APA headquarters. 2. Committee activities from November 1959 to April 1960 have been largely given over to carrying out a project to write up a history of the American Psychiatric Association under topical headings useful to the Commission on Long Term Policies. 3. Committee members have also written papers on historical topics and a number have been published or accepted for publication.

The Council approved the recommendation of the Committee on History of Psychiatry that a librarian be employed at the Central Office to facilitate the development of a library illustrating the history of American Psychiatry provided this can be undertaken within budgetary limitations.

The Committee on Medical Education, chaired by George C. Ham, M.D. has completed the Descriptive Directory of Psychiatric Training in the United States and Canada with the assistance of the Central Office and it is now in press. As a result of the recommendation from this committee and similar recommendations by the Commission on Long Term Policies and the Ad Hoc Committee on Education in Public Hospitals in liaison with the American Psychoanalytic Association, the president-elect, at the request of Council, has appointed a steering committee to develop tentative plans for a conference on the responsibilities, functions and training of psychiatrists and with authority to seek outside funds to support such a conference.

The principal activity of the Committee on Mental Deficiency, under the chairmanship of Howard V. Blair, M.D., was a planning of an exploratory conference on mental deficiency with other organizations with similar interests; this has been approved, in principle, by Council and referred back to the committee for proper implementation. The committee is now

engaged in developing suitable ways and means to hold such a conference.

James V. Lowry, M.D. chairman of the Committee on Public Health, indicates that information has been obtained on the mental health activities of those states in which APA surveys were done prior to July 1957 and finds that there have been impressive changes in these states. Committee members Mabel Ross, M.D. and Benjamin Pasamanick, M.D. actively participated in the Conference on Mental Health Training in Schools of Public Health. Another member, Joseph Downing, M.D., continued to maintain liaison with the American Public Health Association, with particular reference to the American Public Health Association Guide for Evaluating Community Mental Health Programs. The committee has initiated the gathering of information to assist in determining if an action program is necessary and/or practical on nursing home care for psychiatric patients.

The Committee on Rehabilitation has been active through group action and through the activities of individual members, particularly its chairman, Benjamin Simon, M.D. Dr. Simon has been reappointed for another three-year term as the APA representative on the Medical Advisory Council of the American Occupational Therapy Association, and the Council on Medical Education and Hospitals of the American Medical Association has requested his reappointment to several of their Advisory Committees. He has most recently participated in a Survey of the Curriculum in Occupational Therapy of the University of Florida. Action is being taken in regard to the rehabilitative aspects of the APA's Mental Health Surveys of Alabama and British Columbia. Donald Carmichael, M.D. of the committee has participated in the work of the Subcommittee on Mental Health Terminology of the Advisory Committee on Nomenclature and Classifications relevant to disability and rehabilitation and indicates definite progress being made in the development of a standardized nomenclature of disabilities including mental disorders. Active participation is reported by the committee with a number of other organizations in the rehabilitative field. The book *Rehabilitation of the Mentally Ill; Social and Economic Aspects*, edited by Greenblatt and Simon, was published in January of this year and contains several chapters written by members of the committee. Various other papers on rehabilitation have been written by members of the committee. A round table meeting, under the sponsorship of this committee, on "The Impact of the 'Open Door'

on Activity Programs in Psychiatric Services" is being held at this Annual Meeting. The work of the committee will be reported upon at the Eighth World Congress of the International Society for the Welfare of Cripples.

The report of the Committee on Research, Milton Greenblatt, M.D., chairman, is as follows: During the past year, several notable Regional Research Conferences were held. On June 5 and 6, 1959, Galesburg State Research Hospital and University of Illinois presented a conference on "Cerebral Dysfunction and Mental Disturbance." Dr. Harold E. Himwich was honored at this meeting on his 65th birthday.

The New Orleans conference of January 13 and 14, sponsored by Louisiana State University School of Medicine had as its theme, "Problems of Communication." In Seattle on February 26 and 27, the University of Washington sponsored a meeting on "Research in the Behavioral Sciences." The State University of Iowa selected the topic "Child Development and Child Psychiatry" in tribute to Dr. Arnold Gesell in his 80th year, for its conference on March 18 and 19, 1960.

Now in the planning stage for 1960 are conferences in St. Paul, Los Angeles and New Haven.

Several Psychiatric Research Reports have been published recently. Report No. 11, entitled "Recent Advances in Neurophysiological Research," is the proceedings of the conference conducted by McGill University in Montreal in November 1957; and Report No. 12 on "Explorations in the Physiology of Emotions" is a result of the University of Oklahoma's conference in April 1957.

Through the APA Central Office, application has been made for outside funds to finance the proposed conference-workshop on "State and Local Participation in Mental Health Research." This is the conference developed by the GAP Committee on Psychopathology in collaboration with APA's Committee on Research.

At the December 1959 annual meeting of the American Association for the Advancement of Science, the Committee on Research again cosponsored a symposium. "Animal Behavior" was the topic of the two-day conference, arranged by committee representative Dr. Eugene Bliss who, with the permission of AAAS, will have the proceedings of this symposium published, perhaps by Harper.

Dr. Peter Knapp of the committee is presently engaged in plans for a 1960 AAAS symposium with probably collaboration with the American Psychoanalytic Association. The

Committee on Research, represented by Dr. L. J. West, is sponsoring a round table on "Research on Dreams" at the 1960 APA Meeting.

For the 1960 Annual Meeting, Sir Aubrey Lewis of Maudsley Hospital, London, was selected to deliver the Adolf Meyer Memorial Lecture, speaking on "The Study of Defect."

The report of the Committee on Therapy, under the chairmanship of Henriette Klein, M.D., indicates that the committee has completed its two-year study of "The Status of Psychotherapy of Hospitalized Schizophrenic Patients." A preliminary report is ready to be submitted. This study was done through the cooperation of approximately 300 hospitals. The committee has completed the first draft of an "Outline of Therapies :—The Elements of Psychiatric Treatment : A Brief Guide for the Physician." This project has been endorsed by the Committee in Liaison with the American Academy of General Practice. The Committee on Therapy views with increasing alarm the "popularization" of hypnosis as a treatment procedure and particularly the teaching of this technique conducted outside of standard medical sources. The committee has gathered information concerning the use and abuse of hypnosis and has available the various resolutions on this subject passed by different District Branches. The committee is in the process of preparing a statement on "Recovery, Incorporated."

The work of the Ad Hoc Committee on Education in Public Hospitals in Liaison with the American Psychoanalytic Association, under the chairmanship of Bernard Bandler, M.D., has been the preparation of a brochure on "The Patterns of Types of Programs for Education in Public Hospitals" which is predicated on the collating and the organizing of data secured during the last several years from panels and workshops held throughout the country addressed to the needs of public hospitals in relationship to education and personnel. As indicated previously, a recommendation coming from this committee to Council on "graduate education," similar to recommendations coming from other committees, resulted in the appointment of a steering committee by the president-elect to plan for a comprehensive conference in this area.

During my first year as Coordinator, I have been impressed with the scope of committee work and the dedication of the individual members. As a result of my experience, I have a keener appreciation of the fact "—that the work of the various committees is the most important operation of the APA—." Finally, I extend to the chairmen and members my appreciation of their forbearance and cooperation.

Harvey J. Tomkins, M.D.
Chairman

COMMENTS

COLLEGE STUDENT INDISCIPLINE IN INDIA

In an article in *The Guardian* published by Garda College and Baria Science Institute (Navsari, India) Principal A. K. Trivedi and associates throw light on a pressing problem in education in India today. They indicated the major factors in student indiscipline and its principal causes, likewise remedial steps that should be taken.

These findings are based on the responses of 743 students of both sexes from the College and Institute, who volunteered for the test. They were given a questionnaire containing 45 items covering important aspects of student life and were required to write their opinions immediately in the presence of their teachers. In the hope that they would express themselves freely and honestly they were to turn in their papers unsigned. The authors are quite aware of the flaws in the questionnaire method but felt that by asking for spontaneous answers on the spot to questions they had not had time to deliberate or confer about they would get as close as possible to the real attitude of the students. To simplify the process, questions could be answered "yes" or "no" or by simply checking applicable items.

The results showed that the students had surprisingly poor respect for University, College and teachers, while 16% of those answering the questionnaire have no respect even for their parents. The conclusion is that in family and social outlooks "the students are hopelessly ill-prepared in the matter of general respectful attitude towards others." Some of the details of this test are striking: 47% of the parents do not provide the necessary books for their sons and daughters to study; nearly 45% of the students do not read standard texts; many depend on cram books to pass their examinations; "about 20% of parents take

no interest in results, behavior or general manners of their children in their college life"; 68% of the students take an active interest in politics; politicians and outside leaders are substantially responsible for creating an attitude of indiscipline.

The authors sum up that 69% of the students have no love and regard for the University.

It is notable that in the authors' discussion there is no mention of any program on the part of the University for bringing teachers and parents together in the interest of planned collaboration for the benefit of all concerned.

Principal Trivedi and his associates have concrete suggestions for improving the situation: all students should be in residence under University control, with one rector or sub-rector to every 12 students to give advice and be responsible for deportment; scholarship money should be controlled as far as necessary to insure that students be provided with the necessary text books. Small teaching centers are preferred to large ones and it is even suggested that an "overgrown University" might profitably be broken up into two or three smaller ones.

On the constructive side the plan as presented in this brief article in *The Guardian* leaves much to be desired. Its main strength lies in a clear statement of the outstanding difficulties of student life as exemplified in the two institutions mentioned, and pointing to some conspicuous reasons for these difficulties.

In the matter of indiscipline among the youth of this generation in India it is worth remembering, as the authors point out: "Young men do today what their elders did under another Government when they were taught to be disobedient."

CAPITAL PUNISHMENT AS DETERRENT

A few years ago a man was hanged in Alexandria, Virginia. One who witnessed the execution, on that very day, murdered a peddler in the Smithsonian grounds at Washington. He was tried and executed, and one who witnessed his hanging went home, and on the same day murdered his wife.

ACTIVITY OF NIAMID® AGAINST MYCOBACTERIUM TUBERCULOSIS AND CROSS RESISTANCE TO ISONIAZID

Editor, THE AMERICAN JOURNAL OF PSYCHI-
ATRY :

SIR : A new drug, Niamid®, N-isonico-
tinoyl-N'-(B-N-benzylcarboxamido-ethyl)-
hydrazine, recently put on the market for
the treatment of mental depression is closely
related chemically to Isoniazid. The chem-
ical structures of Niamid® and Isoniazid are
as follows :

Isoniazid with resultant loss of the effective-
ness of this drug for subsequent therapy of
the tuberculosis. Further ramifications of
this situation in terms of cross infection of
other psychiatric patients with Isoniazid
resistant tubercle bacilli need not be ex-
plored here.

To investigate this possibility, 3 cultures
of acid-fast bacilli sensitive to 0.1 mcg. of

Because of this similarity, it was thought
that Niamid® might possess anti-tuber-
culous activity. If such were the case, its
administration to psychiatric patients who
also had tuberculosis might result in the
development of resistance of the bacteria to

Isoniazid and 3 cultures resistant to 5.0
mcg. of Isoniazid per milliliter (ml.) of
medium were used to test for sensitivity and
cross resistance to Niamid®. The cultures
were recent isolations for patients hos-
pitalized for tuberculosis.

TABLE 1
SENSITIVITY STUDIES TO ISONIAZID AND NIAMID®

Culture Source	Control	ISONIAZID			NIAMID®					
		Mcg./ml.			Mcg./ml.					
		0.1	1.0	5.0	0.01	0.1	1.0	5.0	20	100
E	4+	S	S	S	CR	CR	S	S	S	S
G	4+	S	S	S	CR	CR	S	S	S	S
P	4+	S	S	S	CR	CR	S	S	S	S
K	4+	CR	CR	CR	CR	CR	CR	CR	CR	CR
R	4+	CR	CR	CR	CR	CR	CR	CR	CR	CR
S	4+	CR	CR	CR	CR	CR	CR	CR	CR	CR

Key :

4+ = confluent growth over entire media surface.

S = no growth.

CR = same as 4+.

A sample of pure Niamid® was obtained.¹ The drug was incorporated into Lowenstein-Jensen medium in the following concentrations: 0.01, 0.1, 1.0, 5.0, 20 and 100 mcg. per ml. of medium. Isoniazid sensitivity tests were done simultaneously at concentrations of 0.1, 1.0 and 5.0 mcg. per ml. of the same medium.

The bacteria were emulsified in physiological saline, and approximately one billion organisms were inoculated on each media slant. Control tubes of Lowenstein-Jensen medium without drug were also used. The cultures were read at 28 days.

The results, as given in Table 1, demonstrate the occurrence of cross resistance in that when the tubercle bacilli were completely resistant (CR) to 5.0 mcg. per ml. of Isoniazid they were also completely re-

sistant to the same concentration of Niamid®, and to concentrations as high as 100 mcg. The table of results also shows that Niamid® is slightly less effective than Isoniazid since it does not inhibit multiplication at as low a level as does Isoniazid.

SUMMARY

This study shows that there is cross resistance of tubercle bacilli to Niamid® and Isoniazid. When Niamid is administered to a patient, thorough studies should be carried out to determine if the patient also has active tuberculosis. If so, a second anti-tuberculous drug should also be used, in accordance with currently established principles of combined drug therapy for tuberculosis.

RE NARDIL

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: In the February 1960 issue of your *Journal*, Dr. U. C. Kothari of Danville State Hospital, Danville, Pennsylvania, has written a paper entitled "Toxic and Other Side Effects of Nardil, Phenelzine Sulphate W1544A." This investigational report contains a number of inconsistencies which we feel merit editorial consideration.

1. *The Cephalin Flocculation Test*—The cephalin flocculation tests, as well as the many other "flocculation" tests, reflect alterations in plasma protein composition. To quote Schiff (*Diseases of the Liver*; Lippincott 1956): "None of these tests is strictly a liver function test, and none is an entirely specific indication of liver dysfunction. the tests must be used intelligently with due regard to the whole clinical picture and not interpreted blindly as though they were specific liver tests."

It is because of this that clinicians employ a so-called battery of tests to evaluate liver function and do not rely solely on a non-specific flocculation test. This would be es-

pecially true in the study of any patient where the laboratory reported an abnormal value for a single flocculation test. In none of the cases reported by Dr. Kothari was any additional laboratory test indicative of liver function reported, such as serum alkaline phosphatase, serum bilirubin, and serum glutamic oxaloacetic transaminase.

Also of interest is the erratic fluctuation in the cephalin flocculation results in certain of the cases reported. One patient had a flocculation test reported as 2+ on one occasion during therapy. The drug was discontinued and then readministered. Despite reexposure to Nardil, all subsequent flocculation tests in this patient were normal. To interpret this single 2+ CCF report as "liver damage" in view of these findings and in the absence of any other clinical or laboratory evidence hardly seems justified. In two other patients the CCF tests are reported as returning to normal despite continuation of the drug. In another patient an "hepatotoxic effect" is ascribed to Nardil solely on the basis of a single 1+ CCF report.

It would have been helpful if the author

had cited additional references. For example, in *The American Journal of Psychiatry*, 116: 71, 1959, Saunders, *et al.*, reports 61 patients treated with phenelzine. They state, "... our patients were subjected to a battery of clinical studies, including thymol turbidity, cephalin flocculation, alkaline phosphatase, A/G and BUN, without significant abnormalities."

2. *Drug Rash*—The author states that "one patient developed a marked drug rash

soon after the first dose of Nardil." The drug was discontinued; but three days later was resumed in standard dosage. Despite reexposure, the rash disappeared and did not recur. In view of this, it would be difficult to classify the observed dermatitis as a "drug rash."

Thomas C. Fleming, M.D.,
Medical Director,
Warner-Chilcott Laboratories,
Morris Plains, N. J.

NARDIL

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: I have read with great interest the paper by Dr. Ujamlal C. Kothari in the Clinical Notes Section of the February *Journal*. In this paper, Nardil (phenylethyl hydrazine dihydrogen sulfate) was reported to exhibit toxic effects on the liver in 7 out of 13 cases as judged by the development of an abnormal cephalin flocculation test. We have just concluded an investigation on the efficacy of Nardil in angina pectoris, and in the course of this study, a battery of liver function tests was performed prior to instituting therapy and while receiving Nardil. The dosage employed was 15 mg. three times a day, identical to that employed in Dr. Kothari's study.

We have found Nardil to be virtually free of hepatotoxicity in the patients studied. Specifically, in 36 patients, no changes in the cephalin flocculation test or in serum bilirubin were noted. Slight elevation of the

serum glutamic-oxaloacetic transaminase occurred in 2 patients, and elevation of the alkaline phosphatase occurred in a single patient. No evidence of clinical hepatotoxicity or drug eruption was encountered.

It should be borne in mind that the cephalin flocculation test, although widely used as a test of hepatic function, is not a specific test of hepatic dysfunction, but merely reflects subtle alterations in plasma proteins not necessarily due to liver disease. Secondly, one is not always justified in considering "one-plus" reactions as necessarily abnormal, because of laboratory variations in technique, stability of reagents, *etc.*

The purpose of this communication is to report that we have found Nardil to be relatively free of hepatotoxicity, and therefore one should not discard a valuable antidepressant drug on the basis of meager laboratory observations.

Elmer Pader, M.D.,
New York, N. Y.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Thank you very much for giving me the opportunity to respond to the letters of Doctor Fleming and Doctor Pader.

In reply to Doctor Fleming, I must say that I could not find "... a number of inconsistencies ..." in my paper entitled "Toxic and Other Side Effects of Nardil" as claimed by Doctor Fleming, but I reported

the facts as I observed them in good faith. Keeping the welfare of the patients in mind, I could not ignore my findings and felt obliged to make them public.

I am unable to accept that all our CCF (cholesterol cephalin flocculation) reports were due to "erratic fluctuation" suggested by Doctor Fleming because: 1. In none of these patients, was the CCF found plus prior to putting them on medication, 2. In

6 of our patients CCF never became plus, 3. In some of them CCF reports were proportional to the dosages of Nardil.

In case of drug rash, Doctor Fleming is in error in stating that the drug "was resumed in standard dosage." My statement was: "(The) patient was placed on smaller doses which were gradually increased to 15 mg. t.i.d. without further reaction." I believe this observation does not indicate that this was not a case of "drug rash" but rather indicates a case of "drug rash" where the phenomena of desensitization or development of tolerance to the drug occurred by the gradual increase of the medication.

In reply to Doctor Pader, I must say that I agree with him that "... one is not *always* justified in considering 'one-plus' reaction as *necessarily* abnormal," but many of our patients had more than "one-plus." I also agree with him that "one should not discard a valuable anti-depressant drug on the basis of meager laboratory observations." Let it be known that I am impressed by the anti-depressant effects of Nardil and I am still using it.

I am not an authority, but personally I cannot discard the widely used liver func-

tion test CCF as it indicates disturbances in the plasma-proteins (*Normal Values in Clinical Medicine*; by Sunderman and Boerner) for which "the liver is the major site of formation." (*Biochemistry of Disease*; by Bodansky and Bodansky). To my mind the plasma proteins are vitally important to health, therefore, any drug causing such changes should be used with caution.

In conclusion, I request Doctor Fleming and Doctor Pader to re-read my paper noting that I did not claim Nardil to be definitely hepatotoxic or that it should be discarded. What I did say was:

"None of them (our patients) developed any clinical sign or symptom of liver disorder." ... "Risk of hepatotoxic effects of this drug is worth keeping in mind." ... "Phenelzine sulphate may produce drug rash as many other drugs do." ... "All the above effects are mild and reversible and may be treated by reducing or discontinuing the medication and with adjuvant therapy."

Ujamlal C. Kothari, M.D.,
Pontiac State Hospital.

PSYCHIATRISTS IN FEDERAL PRISON SERVICE

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: An article by Dr. Warren S. Wille on "Psychiatric Facilities in Prisons ..." which appeared in the December 1957 issue of *The Journal* came to our attention shortly after we printed our 1958 bulletin on personnel employed in State and Federal institutions.

The National Prisoner Statistics series which was initiated by the Bureau of the Census in 1926 was transferred to the Bureau of Prisons in 1950. The Census Bureau began in 1926 to publish statistics on personnel employed in State and Federal prisons and reformatories. This continued through 1946, the year the Census Bureau terminated publication of annual reports on prisoners. In 1950 we published personnel statistics which covered all States but Georgia. We continued to collect the data

but due to lack of staff and also some feeling that the reports were not adequate we hesitated to publish again until 1958. The 1958 figures are based on an entirely revised form which had been in operation for three years.

The study by Dr. Wille indicates that his project covered the year 1954 and that the only previous survey was done by Dr. Winfred Overholser in 1926! Though Dr. Wille's figures are somewhat more comprehensive than those we publish, nevertheless data of psychiatric personnel employed in State and Federal institutions have been available for many years.

James A. McCafferty,
Criminologist,
U. S. Dept. of Justice,
Bureau of Prisons,

REPLY TO FOREGOING

Editor, *THE AMERICAN JOURNAL OF PSYCHIATRY* :

SIR: In comparing the statistics on the number of psychiatrists employed in State and Federal prisons in 1954 (the basis for the previous article in this *Journal*) and the number employed in 1958 as listed in National Prisoner Statistics, No. 22, January 1960, Federal Bureau of Prisons, Washington, D. C., a total of 43 full time psychiatrists were employed in 1954. Of these, 31 were working in the State prison system and

12 for the Federal system. The 1958 figures reveal a total of 43 psychiatrists employed full time, 32 in the State institutions for adult offenders, and 11 for the Federal institutions, revealing that the acute shortage of psychiatrists in corrections work still persists.

State Prison of Southern Michigan

INDUCTION VS. DEDUCTION

The conflict between Galileo and the Inquisition is not merely the conflict between free thought and bigotry or between science and religion; it is a conflict between the spirit of induction and the spirit of deduction. Those who believe in deduction as the method of arriving at knowledge are compelled to find their premises somewhere, usually in a sacred book. Deduction from inspired books is the method of arriving at truth employed by jurists, Christians, Mohammedans, and Communists. Since deduction as a means of obtaining knowledge collapses when doubt is thrown upon its premises, those who believe in deduction must necessarily be bitter against men who question the authority of sacred books.

NEWS AND NOTES

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—Two examinations have been set up for 1961. The first will be held in New Orleans, Louisiana, on March 20 and 21, 1961, and another examination has been set up for October 9 and 10, 1961, in Chicago, Illinois.

CANADIAN MENTAL HEALTH ASSOCIATION ANNUAL MEETING.—More than 200 delegates registered for the annual meeting of the C.M.H.A. at Banff, Alta., June 2-4, 1960. The leading speakers included Dr. J. S. Tyhurst of Vancouver, Dr. Frank Coburn of Saskatoon, Dr. Keith Yonge of Edmonton, Dr. Paul Lemkau of Baltimore, Rev. Dr. Noel Mailloux of Montreal and Dr. James Gilbert of Aberdeen, S. Dakota.

Dr. Tyhurst declared that "a patient's progress depends a great deal on the way a staff appears to expect him to behave. Where the emphasis is on safe custody and control patients appeared to have behaved with 'repressed disturbed behaviour'; wherever they are treated in a way that lets them see the staff expect them to get better, they do, in fact, begin to get better . . ."

Dr. Coburn's forthright statement: "The day of the old-fashioned deterioration-breeding medical concentration camp called an asylum is just about over. The day of short-term treatment in small units with restitution to the community is here . . . The new concept is that a great many mental patients can be treated in the community with safety and dignity. It is the job of the CMHA to see that these revolutionary concepts are known, accepted and implemented the length and breadth of this fair land."

Dr. Paul Lemkau, Professor of Public Health Administration at Johns Hopkins University, referring specifically to problems in the rehabilitation of mental patients, stated that the heart of the solution lies in preventing debilitation through improper treatment procedures still prevalent in the traditional and understaffed hospital. It is his opinion that removing a patient from his community, isolating him from his fel-

lows, can hardly avoid development of an unhealthy attitude.

Rev. Noel Mailloux, distinguished psychologist and director of the Human Relations Research Centre in Montreal, is the recipient of CMHA's first national research award for his studies in juvenile delinquency.

Dr. Keith Yonge, head of Alberta University's psychiatry department gave a splendidly detailed review of the current status of mental health research.

The C.M.H.A., formerly the Canadian National Committee for Mental Hygiene, has an enviable record since its birth in 1918 in the promotion of mental health in Canada. It is the first of fifty-odd national organizations that were established following the original National Committee which was set up by Clifford Beers in New York City in 1909. Dr. J. D. Griffin is Director of the Canadian Mental Health Association.

AMERICAN ELECTROENCEPHALOGRAPHIC SOCIETY.—The newly elected officers of the American Electroencephalographic Society, elected at the June 1960 meeting in Cape Cod, Mass., are as follows: President, Dr. Jerome K. Merlis, Baltimore, Md.; President-Elect, Dr. Charles E. Henry, Hartford, Conn.; Secretary, Dr. George A. Ulett, St. Louis, Mo.; Treasurer, Dr. Isadore S. Zfass, Richmond, Va.

LOS ANGELES CO. DEPT. OF MENTAL HEALTH.—In order to coordinate and further develop its community mental health program under California's Short-Doyle Act, the County of Los Angeles has established a Department of Mental Health. Harry R. Brickman, M.D., F.A.P.A., formerly in charge of the outpatient department of the U.C.L.A. Neuropsychiatric Institute, is director of the new Department.

The Short-Doyle Act (1957), was designed to encourage the development of local mental health services through a 50% state reimbursement formula. Services allowable under the Act are voluntary psy-

chiatric outpatient, inpatient, and rehabilitation programs, psychiatric consultation, and mental health education.

All five of these services are represented in the Los Angeles program, which began with a total budget of slightly over \$1 million. Clinical services are concentrated almost entirely in tax-supported county general and chronic disease hospitals, while mental health consultation and education programs are planned for the County Health and Schools Departments. Preventive services and careful program evaluation are to be emphasized in the Department's future growth.

Two unique programs are being developed: 1. A psychiatric treatment program for delinquent children and their families to be conducted jointly with the County Probation Department on a voluntary child-guidance basis, with agreement by juvenile court authorities to suspend court wardship in favor of treatment efforts; 2. A county-wide psychiatric consultation service, in which the talents of the large pool of privately-practicing psychiatrists in Los Angeles are being made available in consultation with a wide variety of community health, education, welfare, and correctional agencies.

Since organized opposition to mental health programming has had a telling effect in Los Angeles, it is worthwhile to note that active participation by local psychiatrists in the deliberations of the Los Angeles County Medical Association was a strong positive factor in the Association's support of the new Department. The Southern California District Branch acted as an effective rallying point for this community action on the psychiatrists' part.

CONFERENCE ON "METABOLIC ERRORS, GENETICS AND MENTAL DISEASE."—The Second Invitation Conference presented by Napa and Sonoma State Hospitals in cooperation with the Ames Company, Inc. will be held at Napa State Hospital, Napa, Calif. on Saturday, October 8, 1960. The meeting will be limited to 120 professional persons including psychiatrists, psychologists, biochemists, geneticists, pediatricians and other interested persons.

The participants include: David Yi-Yung Hsia, M.D., Assoc. Prof. Pediatrics, Northwestern University Medical School; Norman Kretchmer, M.D., Prof. Pediatrics, Stanford University Medical School; Stanley W. Wright, M.D., Assoc. Prof. Pediatrics, U.C.L.A. Medical School; Willard R. Centerwall, M.D., Asst. Prof. Pediatrics, College of Medical Evangelists; Alfred G. Knudsen, M.D., Ph.D., Chairman, Dept. Pediatrics, City of Hope; Jon Karlsjon, M.D., Chief of Research, Sonoma State Hospital; Carolyn F. Piel, M.D., Asst. Prof. Pediatrics, University of California Medical School, and Robert W. Day, M.D., M.P.H., Research Specialist, Sonoma State Hospital.

For further information write: Dr. David Wardell, Chief of Professional Education, Sonoma State Hospital, Eldridge, Calif.

THE ALLAN MEMORIAL INSTITUTE OF PSYCHIATRY, MCGILL UNIVERSITY.—Dr. D. Ewen Cameron attended the second meeting of the Collegium Internationale Neuro-Psychopharmacologium, in Zurich, July 4-7. He presented a paper: "Further Studies Upon the Effects of the Administration of Ribonucleic Acid in Aged Patients Suffering from Memory (Retention) Failure," (Co-authors: Leslie Solyom, M.D., and Lee Beach, M.A.).

Dr. Cameron also represented the Canadian Psychiatric Association at the annual meeting of the Royal Medico-Psychological Association held in London, England, July 11-15, and discussed with the members the Third World Congress to be held in Montreal June 4-10, 1961.

DR. EDITH BUYER.—The death of Dr. Buyer occurred on June 5, 1960 at Suffern, N. Y. at the age of 66.

A member of the APA since 1947, Dr. Buyer had been medical supervisor to the Board of Education in New Rochelle, N. Y. for many years. She graduated from Johns Hopkins school of Medicine in 1918, and did graduate work in Vienna, Lausanne and Paris. For several years she was assistant in psychiatry at Columbia University.

During World War II she was a Navy

Medical Officer at the WAVES Training School in the Bronx, New York City. She had also served the New York State De-

partment of Health as a supervisor of children's hygiene centers. She was a member of the American School Health Association.

IMITATIVE ANIMAL

For imitation is natural to man from his infancy. Man differs from other animals particularly in this, that he is imitative, and acquires his rudiments of knowledge in this way ; besides, the delight in it is universal.

—ARISTOTLE

CONVERSATION

There is a sort of knowledge beyond the power of learning to bestow, and this is to be had in conversation ; so necessary is this to understanding the character of men that none are more ignorant of them than those learned pedants whose lives have been entirely consumed in colleges and among books.

BOOK REVIEWS

INSULIN TREATMENT IN PSYCHIATRY. Edited by Max Rinkel and Harold E. Himwich. (New York: Philosophical Library, 1959, pp. 380. \$5.00.)

Anyone who is anybody is fashionable. Nowhere is this better seen than in medicine. The human weakness of the physician is far greater than his strength as an independent scientist. Too often he falls in with the enthusiasm of the group; too easily he discards what is of value because of the changing fashion.

As with other fashions, some daring initiator is first rejected, then endured, then embraced, and then rejected. And the intelligence of the physician appears to play a minor role in this acceptance or rejection. So it has been with the insulin shock therapies. I recall an early statement made by one who became a foremost investigator in the field of shock therapy. When the first reports as to their use arrived in America, he exclaimed, "I wouldn't give shock treatments to a dog or even to a rat."

What is the true value of insulin shock for the psychoses? Since Sakel first introduced his procedure in 1927, many thousands of reports on the subject have appeared. After the initial period of rejection, there was wide acceptance; now that the fashion of the tranquilizers has captured the medical imagination, there is doubt again. That the shock therapies were of inestimable value in focusing man's mind on the physiologic aspect of the psychoses is clear. The question now is just how valuable is the procedure itself. Many state hospitals which formerly used it no longer do so. Are they discarding what is of intrinsic value?

In this volume 19 authorities have presented formal papers and a score more have added their comments. Two of the papers provide an excellent historical background. There are 4 stimulating articles on physiochemical research.

Thirteen articles are devoted to clinical research. There are detailed presentations of techniques and thoughtful discussions of the results. Practically all of the contributors agree that insulin shock has definite value; their disagreement concerns the comparative value of insulin versus that of the tranquilizers. Hans Hoff insists that the insulin shock therapy is the only true biologic therapy for paranoid schizophrenia and that the tranquilizers "can only improve symptoms." Although he agrees that through the effect of tranquilizers on

symptoms, the patient's relationships can be improved and a beneficial cycle thus created, he insists that these drugs are for symptom therapy only. Dussik claims an extraordinarily high percentage of results with insulin and explains the failures of others in terms of lack of individualization in the therapy and failure to use the specifically prescribed procedure recommended by Sakel.

On the other hand, many of the authors find that the tranquilizers have adequately supplanted insulin for most of their schizophrenic patients. More patients improve with tranquilizers, they find, than with insulin. Yet even most of these authors agree that there are a number of patients who will respond only to insulin.

One major fact stands out in the presentations. Insulin shock therapy is but *one* of the tools in the total therapy. By itself, it often fails to bring about the desired results. Not only do many of the authors combine insulin with electric shock, but practically every therapist insists on the simultaneous use of psychotherapeutic procedures. The Vienna clinic, for example, uses group psychotherapy, occupational therapy, group dancing and gymnastics; and since domestic exigencies can aggravate the situation, relatives are included in special group psychotherapy. Even Dussik, the staunchest advocate of Sakel's procedure, evidences keen understanding of his patients' psychologic needs and apparently goes to great lengths to care for them.

Yet psychotherapy alone—even the undirected, attenuated form involved in manifesting a personal interest in a patient fails, and as Sargant reports, before the advent of insulin shock therapy psychotherapy given for months was ineffective.

The over-all impression gained from this book is that insulin shock therapy remains a most effective therapeutic procedure, that its effectiveness is greater if the specific Sakel technique is used, and that psychotherapeutic procedures enhance the results. One gains the impression even from those who use insulin, that the tranquilizers are a mighty addition to the psychiatric armamentarium and can be substituted in many cases which formerly were well treated by insulin. These authors agree that where the tranquilizers fail, deep insulin comas should be attempted.

Dr. Rinkel and Dr. Himwich are to be con-

gratulated. To the gargantuan task of enlisting so many outstanding scientists from so many countries they have added a meticulous and perceptive editorship. It would perhaps be carping to mention the absence of a subject index in a book so beautifully printed, with such superior format, and so well organized. Every psychiatrist will find in this volume material not only of specific value in the management of his patients but substance which will aid in his own understanding of psychiatrists, psychiatric procedures, and the pitfalls in the progress of man.

Chicago, Ill.

UEBER DAS SENIUM DER SCHIZOPHRENEN. ZUGLEICH EIN BEITRAG ZUM PROBLEM DER SCHIZOPHRENEN ENDZUSTÄNDE. By *Christian Müller*. (Basel/New York: S. Karger, 1959. IV, pp. 84. sFr. 13.50.) (Bibliotheca Psychiatria et Neurologia Fasc. 106.)

This monograph is based on 101 schizophrenic patients (40 males, 61 females) aged between 65 and 92 years. The material was investigated in the psychiatric department of the University of Lausanne, Switzerland (Chairman: Professor H. Steck). The average age of the patients was 72.3 years, the average duration of the disease 35 years, the average stay in the hospital 25 years. The author found it impossible to divide his material into the usual subgroups; he was astonished about the predominance of paranoid symptoms (main topics: sex, food, nihilism). He differentiates cases with the picture of normal aging from others with more or less clear cut senile-arteriosclerotic manifestations. There is a goodly number of patients who develop into a benign, quiet old age, but also such cases that turn into a particular senile paranoid picture. Among the patients who make their peace with old age as well as among those who deteriorate in the senile arteriosclerotic way, there are quite a few who are no longer recognizable as schizophrenics.

The author points out that his material—all patients hospitalized for many years—is a selected one and that the investigation of old schizophrenics living at large might change the total picture to some degree. He stresses the importance of evaluating clinical (institutional) material without losing sight of the psychotherapeutic and pharmacological treatment of the schizophrenics. He makes the suggestion to do some research in schizophrenics treated with chlorpromazine or reserpine from the viewpoint of "artificial aging" (Künstliche Vergreisung).

This monograph is the result of most meticulous and critical research. It is full of interesting observations and suggestions which in this review can scarcely be alluded to. The author states at the end of the treatise that while carrying on this investigation he found notions like "process" or "defect" in respect to schizophrenics more and more questionable. There is no doubt that every schizophrenic's affliction is a decisive factor in his unique destiny.

EUGEN KAHN, M.D.,
Houston, Tex.

MEHRDIMENSIONALE DIAGNOSTIK UND THERAPIE. By *Ernst Kretschmer*. (Stuttgart: Georgthieme, 1958, pp. 308. \$8.60.)

This volume was published to honor Professor Ernst Kretschmer on his 70th birthday. Kretschmer's influence on psychiatric thinking and practice is well illustrated by the contributions. The title, "Pluridimensional Diagnosis and Therapy," emphasized a contribution to psychiatry which is little recognized in this country. This concept formulates that in any psychiatric disorder, one must try to determine the constitutional factors, the psychologic mechanisms and the neurogenic factors. It was an attempt to find the causative components of an illness and to understand the individual differences instead of attempting to fit all illnesses into Kraepelin's classification. Kretschmer followed in time, but not in thinking, A. Meyer's reaction types. His next step was to apply this pluridimensional concept to psychotherapy.

A broad application of this diagnostic concept by Ruemke is followed by an excellent historical review by Tellez. The current far reaching influence of Kretschmer's concept of constitution on Spanish psychiatry is presented by several Spanish authors. German contributions discuss the significance of constitutional studies in epilepsy, traumatic psychoses, biology and genetics.

The contributions in the broad field of psychopathology might well be considered the most valuable part of the book. These are reformulations of Kretschmer's "sensitive delusional reactions" (1921) by Klaesi, Pauleikhoff and Haefner, and by other authors of the concept of schizophrenic psychopathology. Janz offers an especially stimulating review of the concept of split personality and of the changing psychopathology during the past forty years.

Kretschmer's concept of pluridimensional diagnosis and treatment is further illustrated

by contributions from the clinical field, e.g., in depression, psychogenic and neurotic disorders, social maladjustments.

The psychotherapeutic discussions are viewed essentially from a phenomenologic and existentialistic point of view. However, one should mention two psychotherapeutic methods which illustrate Kretschmer's influence; one, catharsis and the other, the means of hypnoid visualization.

This book offers the reader an understanding of an influential aspect of current German psychiatry, especially in psychopathology and clinical psychiatry.

OSKAR DIETHELM, M.D.,
The New York Hospital,
New York, N. Y.

PSYCHIATRY IN MEDICAL PRACTICE. By W. Lindsay Neustatter, M.D. (London: Staples Press, 1958, pp. 311. \$8.00.)

The author states in the preface that this book will primarily concern those in general practice. Much useful information is contained in the volume, but it would appear that from time to time the author forgets his primary goal.

The format and indexing of the book are such as to assume a degree of psychiatric sophistication in the reader. The contents deal largely with psychiatric entities and touch all too briefly on the application of psychiatric concepts and principles in general medical practice.

No attempt has been made to discuss marriage problems as such. The common problems of middle life, retirement and old age are given little attention; psychophysiologic disorders are generally ignored. The management of psychiatric problems of medical illness and convalescence is not covered. Community resources such as social agencies and others are mentioned but little.

Psychoanalysis and other specialized treatment techniques are described. While these are no doubt of some interest to the family doctor, they can hardly be considered as methods adapted in any way to the general practitioner's use. Treatment procedures such as insulin coma therapy are covered in considerable detail. Cerebral surgery is dealt with more than is necessary in a book of this type. It would seem that a greater effort should have been made to outline methods of treatment applicable to general practice.

Quite naturally, terms in more common use in England than in America have been utilized (e.g., pharmacologic terms such as phenobar-

bitone, largactil and soneryl). The chapter on medico-legal problems will certainly be of value to the physician practicing in England but is of little use to the American physician.

On the positive side it can be stated that there is much valuable information in this book. The chapter on sexual disorders and anomalies is interesting and the disorders of childhood are covered in a rather down-to-earth and practical way.

ROBERT A. MATTHEWS, M.D., AND
HARRY R. DRAPER, M.D.,
Philadelphia, Pa.

PSYCHOTHERAPY BY RECIPROCAL INHIBITION.
By Joseph Wolpe, M.D. (Stanford: University Press, 1958, pp. 239.)

This important book offers what may prove to be the first effective challenge to the pre-eminence of permissive psychotherapies in America today. It describes with great clarity and detail a set of directive psychotherapeutic methods, supported by a critical and detailed analysis of their results. This indicates about a 90% improvement rate which is sustained over a 2 to 7 year follow-up period. Though the possibility of a favorable bias in the analysis cannot be entirely eliminated, with all allowances for this the results are impressive, and should finally dispel the widely held superstition that directive methods aimed at symptom relief cannot produce durable improvement.

The author attributes the effectiveness of his methods to reciprocal inhibition of anxiety by eliciting responses incompatible with it. About half the book is an attempt to support this hypothesis through an exposition of pertinent aspects of conditioned reflex theory, supported by results of animal experimentation. Although both the theory and its applications have shortcomings, they are presented in a lucid and stimulating way.

The reader who approaches this book without prejudice cannot fail to be impressed with the power and ingenuity of the author's thinking, and the earnestness of his efforts to get at the real facts of the psychotherapeutic process. By offering an acceptable theoretical framework for directive forms of therapy and convincing data on their effectiveness, the book may help to free American psychiatrists to experiment more widely with techniques which have considerable therapeutic promise. As such, it deserves the careful attention of all students and practitioners of psychotherapy.

JEROME D. FRANK, M.D.,
Stanford, Calif.

ETIOLOGY OF SCHIZOPHRENIA. By G. U. Malis. (Moscow : Government Publications of Medical Literature (Medgiz), Moscow, 1959, pp. 224. 8.40 rubles.)

In the past generation we have seen so many dragons slain by the St. Georges bearing the emblem of Aesculapius that we are led to believe that all our medical ills will yield to the sharpened spears of the scientist. We have seen consumption proven to result from the bacillus of Koch, malaria to be caused not by the miasma of the swamp but by the organism of Laveran, what was formerly a species of mania (dementia paralytica) to result from the spirochete of Schaudinn. Since the birth of microbiology, there have been repeated attempts to marshal evidence that schizophrenia is due to a toxin, infection, or metabolic dysfunction. Among such endeavors have been Papez with his intracellular vibrios, more recently Heath and Co. with their taraxenin. Yet schizophrenia remains the Erlkönig of the psychiatric world, for it has never been accepted, in spite of these myriad efforts, that there is a specific toxin or a specific histology responsible for the mental symptoms.

Had we not suffered so many frustrations in the past in following the will o' the wisp of schizophrenic etiology, this logical exposition of Professor Malis would convince us that at the basis of schizophrenia are toxic substances probably arising from a virus infection. The 7 chapters of this interesting book describe the characteristics of schizophrenic blood; the effect of this blood on the growth of tadpoles; the effect on the isolated heart of the frog; the toxic substances obtained from schizophrenic blood; the phytotoxic properties; the origin of these properties and their infectious nature; the virus factor in the pathogenesis of schizophrenia. The bibliography contains about 200 Russian references and upwards of 150 non-Russian. The experiments, most of which have been carried out by Malis in the past decade or so, are reported factually along with their controls, and although there is wide variation between the effects from different groups of schizophrenics, the difference between controls and patients is often very impressive. The language is in a clear Russian style.

If one finds himself transported by enthusiasm with these Russian experiments, he should, as an antidote, read the critical evaluation of biochemical research in schizophrenia by Kety in *Science*, June 5 & 12, 1959.

W. HORSLEY GANTT,
Baltimore, Md.

PICTORIAL HISTORY OF PHILOSOPHY. By Dagobert D. Runes. (New York : Philosophical Library, 1959, pp. 406. \$15.00.)

The indefatigable Dr. Runes has done it again. His huge *Treasury of Philosophy* (1280 pp.), published in 1955, presents a wide sweep of the great, the near great and perhaps some others, who have talked about philosophy and other matters that may be something like it.

The present volume in much larger format (11 x 8½ x 1¼ in.) has a still wider sweep because it is given over mainly to pictures which are accompanied by brief biographical sketches and summaries, not by extended excerpts from the writings of the philosophers as in the other book.

Here will be found pictures gathered painstakingly from many sources—960 of them—photographs, reproductions of famous paintings, engravings, sculptures, views of places, portraits of individuals and groups, a veritable picture gallery not such as likely to be found elsewhere assembled in one place. The coverage ranges from Ur of the Chaldees to the contemporary Western world.

The author's introductory words are rather discouraging as to the uses of philosophy in the modern scientific era. "The history of scientific and technical discoveries fails to provide a single clue proving the influence of philosophical methodology . . ." and then, a side glance at certain eminent physicists whose names have been almost household words, who "have dabbled a bit in metaphysical cogitations, but more as a matter of frills than fundamentals."

We are reminded that for many centuries philosophy and theology were inextricably mixed, and neither as such has contributed to the advancement of science. Philosophy has been called in to support all kinds of doctrine theological, social and political, "by reformers as well as reactionaries, by usurpers as well as traditionalists, by kings and conquerors, to make vile and devious acts appear to be God-ordained or a plan of public welfare."

All these things are exemplified in the pronouncements of the spokesmen pictured in this book. One can select that with which one agrees. To seek to digest the whole one needs the power to resolve pre-Creation *tohu-vohu*.

The index lists some 825 names, more or less. The systematic presentation begins with Judaism (44 pp.) including a special section on Spinoza. Then follows Indian philosophy (16 pp.), the philosophy of China (8 pp.), Greece, including Greek thought in Roman lands (44 pp.). Then comes Christianity, pro-

loguing the Dark Ages (35 pp.), the Humanists (17 pp.), the Reformation (5 pp.), the world of Islam (7 pp.), thinkers of France (43 pp.). Here we are even treated to pictures of Sartre and his follower de Beauvoir, then Shaw (2 pp.), the new Italy (7 pp.), the smaller countries (3 pp.), British thinkers (44 pp.), Germany (68 pp.). This section exceeding all the others in length ends anticlimactically with Heidigger, who "for years idolized Hitler as the great protagonist of a new European culture." Finally Russia (14 pp.), America (43 pp.).

A rich feast is here for the Gargantuan appetite. Individual sections may include not only philosophers in the more technical sense, but also poets, dramatists, scientists, mystics, educators, pulpit orators, historians, psychologists. Brief sketches run from a few lines to half a page; longer ones, e.g., Spinoza, Plato, Darwin, Goethe, Franklin, Voltaire, Dewey, may occupy 2 or 3 pages each.

A vast amount of information is crowded into this volume, and emphasis is by intention placed upon the pictorial features. (There is, for example, a full page detail from the School of Athens.)

It is not to detract from the interest and value of Dr. Rune's gigantic *opus* to say that on reaching the final page one is more perplexed than ever in attempting to find an answer to the question in the author's initial Word to the Reader: "What is this metaphysical world, inhabited by so complicated and divergent a population, all about?"

C.B.F.

THE INEFFECTIVE SOLDIER—LESSONS FOR MANAGEMENT AND THE NATION. VOL. 1 THE LOST DIVISIONS. VOL. 2 BREAKDOWN AND RECOVERY. VOL. 3 PATTERNS OF PERFORMANCE. By: Senior Author *Eli Ginzberg* and Collaborators: *James K. Anderson, Sol. W. Ginsberg, John L. Herma, John B. Miner.* (New York: Columbia Univ. Press, 1959, pp. 225, 284, 340. \$6.00 per vol.)

These volumes represent the reports of The Conservation of Human Resources Project, established by General Eisenhower in 1950. The Project was a co-operative research undertaking, involving Columbia University, the business community, foundations, trade unions and the Federal Government. Since 1955 the Project has been under the administrative supervision of Dr. John A. Krout, Vice President of the University.

This statement is more properly cast in the form of an announcement rather than a review

in the traditional sense. The over-all enquiry had to do with an assessment of military experience in regard to man-power problems in the U. S. Army during World War II, and some of the implications (partly substantiated by post-war follow up) for national civilian human economy.

Volume 1 provides background data gathered from Army and Veterans Administration records, on men who were rejected for service or had to be prematurely separated from service by reason of psychological unsuitability.

Volume 2 presents an analysis of 79 case histories of soldiers who "failed."

Volume 3 provides an over-all view of the Project and endeavours to carry the analysis towards a deeper understanding of performance in war and peace.

There can be no question as to the worthwhileness of the medical-social science contribution thus reviewed, to war-time problems of military organization and training. Those who participated in, and gave leadership to, the understanding and solution of these problems had a challenging and exciting experience, much of which was definitely pioneer in nature. There can be no question, also, as to the importance of the search for the relevant correlates of that experience in civilian social life.

Since, however, we are never dealing with personal breakdowns and inadequacies *in vacuo*, but human beings engaged in a manifold of social demands and opportunities, we can never lose sight of the fact that military organization in time of war—and more specifically in time of World War II—is very different in our culture from pre- and post-war civilian organization. The Project recognizes this, in large part. Yet "Lessons for Management and the Nation," as a significant sub-title of the Reports, *in toto*, may suggest at least some elements of a somewhat naive and unacceptable social philosophy. The reader is challenged to review the military evidence in the light of such necessary considerations.

W. LINE, PH.D.,
University of Toronto.

THINKING. By *Sir Frederick Bartlett.* (New York: Basic Books, 1958. pp. 200. \$4.00.)

The approach to the subject of thinking in this book is from the viewpoint of the experimental psychologist. From some amazingly simple, but yet ingenious experiments, fascinating, but not altogether unexpected, results appear concerning several modes of thinking

and the differences between people when faced with an intellectual problem. These experiments were conducted at the Psychological Laboratory of the University of Cambridge, England, where Sir Frederick Bartlett was Director and Professor of Experimental Psychology until his retirement in 1952.

This experiment is an example. Individuals were presented with the following number arrangement :

1 2 3 4 : 2 1 3 4 : 2 1 4 3 : . . .

The subject was "asked to continue to change the position of the numbers in successive steps until he reached an arrangement at which it seemed 'natural' or 'sensible' to stop." . . . most people confronted with this example simply went on changing the positions of numbers in a haphazard manner until they were tired, or until a halt was called. But an appreciable number did extrapolate by rule, . . . confining changes of position to first and last pairs only and producing :

1 2 3 4 : 2 1 3 4 : 2 1 4 3 : 1 2 4 3 : 1 2 3 4

The *a priori* complete series was :

1 2 3 4 : 2 1 3 4 : 2 1 4 3 : 2 4 1 3 : 4 2 1 3 :
4 2 3 1 : 4 3 2 1

Not many reached it.

Quantifiers such as "most" or "an appreciable number" are characteristic of this work. From this experiment the reader might gather, although it is not the author's point, that most people don't think.

The author makes it clear : "Thinking is, in my use of the word, not simply the description, either by perception or by recall, of something which is there, it is the use of information about something present, to get somewhere else." There is comment that this kind of thinking demands intelligence, but intelligence is not a subject of study in this book. No attempt is made to measure either the quantity or quality of "thinking" or intelligence. It is the apparent purpose of the book to describe what thinking consists of.

There are descriptive and experimental essays on Interpolations (filling in gaps), Extrapolation (thinking beyond what is presented to a conclusion), sifting out evidence, thinking in experimental science, in everyday life, and in artistic productions. These essays cover only that part of the ground that the author has personally studied. There is no discussion of neurophysiology, no study of delusional thinking or other thinking disorders, nothing much about individual differences except to point out that such differences appear, the mathematical formulation of thinking is not included, and there is nothing about the unconscious.

The book is a short one, 200 pages, and a personal one. Among other things about thinking, one gets a good idea what Sir Bartlett's thoughts are ; and that is very likely the way he intended it to be.

PAUL W. DALE, M.D.,
Greenwich, Conn.

PSYCHOLOGICAL STRESS. By Irving L. Janis.
(New York : John Wiley & Sons, 1958,
pp. 439. \$6.95.)

In *Psychological Stress*, Irving L. Janis offers a comprehensive and important study of the psychological reactions of surgical patients. The author brings to this work a unique blending of detailed and sophisticated knowledge of the literature of psychological stress with a competent handling of 3 different research techniques. In the first part of this book he presents a detailed and extended fragment of a psychoanalytic case study of a single patient during the period when she was undergoing surgery. The depth and richness of understanding of this patient's experience are then amplified and in the next part through intensive interviews of a small number of surgical patients and a questionnaire survey of a large number of surgical patients. The net result is a sensitive and illuminating account of the psychological reactions to impeding surgery and during the postoperative period, as well as the interrelationships between these two.

The first part is offered both as a model for the research use of psychoanalytic techniques and for its findings with regard to stress. In keeping with the first aim, there is a careful and considered discussion of the problems and areas of applicability of psychoanalytic procedures. Most of the important issues are dealt with, and if the result is not final or complete, it is at least a notable step forward. Perhaps most lacking is any adequate way of preventing the investigator's research interests from influencing the reports of the Subject. They almost certainly did in this instance. With regard to content, the psychoanalytic study arrives at the general hypothesis that, "in adult life, exposure to any signs of potential mutilation or annihilation will tend to reactivate the seemingly outgrown patterns of emotional response which had originally been elicited and reinforced during the stress periods of early childhood." This is, of course, classical psychoanalytic doctrine and could have been stated in advance of the inquiry. However, the evidence certainly very strongly supports this hypothesis which is further elaborated in 14 subsidiary hypotheses.

The second part of the book, dealing with pre- and post-operative interviews and daily behavioral records of a small number of surgical patients plus the larger questionnaire survey, throws light on some of the hypotheses developed in the first part and in addition produces further hypotheses dealing with the specific relationships between the level of anticipatory fear and subsequent adjustment. The techniques are skillfully handled and the interpretations sensitively drawn throughout. The net result is a convincing picture of the psychological life of a surgical patient.

It is precisely because this book offers such an outstanding contribution to this area that the reviewer regrets the selection of a title for the work which implies far more than is offered. This book is not a general treatise on psychological stress. It is true that in reading it one learns a great deal about stress; the author's wide knowledge shows clearly throughout and he is careful to point out areas of relationship to other types of stress situations and possible generalizations growing out of these. At the same time he is equally careful to warn against overgeneralization, and himself professes this work to be no more and no less than it is, a fine study of the psychological reactions of surgical patients.

The reader who approaches this book with this in mind will be richly rewarded. All those concerned professionally with psychological studies will find the book fascinating reading. The researcher will be stimulated by its obvious scholarship, its illuminating insights, and its careful generalizations; the practitioner will gain increasing understanding of a hitherto much neglected area of human experience. But this book deserves a wider audience. It, or preferably a condensed summary might well be made required reading for physicians, nurses, hospital administrators, and all others professionally concerned with the care and treatment of surgical patients.

ENVIRONMENTAL INFLUENCES ON PRENATAL DEVELOPMENT. Edited by *Beatrice Mintz*. (Chicago: University of Chicago Press, 1958, pp. 87. \$3.00.)

This is one of the reports of the Developmental Biology Conference Series which took place under the auspices of the National Academy of Sciences. The complete record is now available in 10 volumes. The present volume is reviewed here primarily in order to draw the

attention of students of human behavior to a new and reliable source of information relating to the effects of prenatally experienced influences upon the development of the organism. Virtually all the material discussed in this formal record of an informal series of conferences is based on and refers to lower animals, but it is just such materials that can give us insights into what probably happens *in utero* to the human conceptus. If it is true that severe emotional disturbances in some pregnant women during the first trimester can give rise to sufficiently changed enzymatic states to produce cleft palate in the offspring, may it not be that such disturbances leave a permanent imprint also upon the nervous system? These are questions to which we need verifiable answers. Meanwhile, the present volume will serve to afford the markers in the direction of which one should look. There is an introduction by Paul Weiss, and the 8 chapters deal with the following matters in clear and concise English: 1. "Experimental alteration of morphogenesis: medical and biological significance"; 2. Specificity of teratogenic agents, of responding tissues, and of time of interaction; 3. Extragenic factors causing variations in development; 4. Interaction between the early embryo and its environment; 5. Multiplicity of effects of teratogenic agents; 6. Nutritional requirements for morphogenesis: action of metabolic inhibitors; 7. Interaction of areas of growth; 8. Developmental relationships and interactions in time and space.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

LIVE AND LET LIVE. By *Eustace Chesser*. (New York: Philosophical Library, Inc., 1958, pp. 126. \$4.75.)

The author of *Live and Let Live* is a psychologist with a flair for sociology. He has written extensively on love, marriage and sex. His latest venture treats of homosexuality, chiefly in the male, and of prostitution.

The sub-title of *Live and Let Live* is—*The Moral of the Wolfenden Report*. Essentially it is a plea for tolerance; that the deviant be not considered a *prima facie* criminal to be hounded by the police and prosecuted in the courts. The plea is well made, and will be concurred in by the informed.

However, the author is not content merely to plead. He changes roles and becomes the expositor of questionable propositions and the expounder of odd theories. Thus—"The crack troops of Sparta and Thebes—consisted of pairs of homosexual lovers." "The great major-

ity of homosexuals merely indulge in an affectionate relationship." "If the universe is indeed the outcome of a design then homosexuals . . . must be part of that design." This is further elaborated in the affirmation, "Nature does nothing in vain, therefore the homosexual and the bisexual as well as the heterosexual must surely have a place in the scheme of things."

The author is absolutely certain that some percentage of homosexuality is congenital, and that the reason why "public revulsion is so strong" is because "unconsciously, if not openly, we envy those who do what we ourselves would like to do but dare not."

Dr. Chesser's desperate argumentation is perhaps understandable in the light of Britain's savage persecution of the homosexual. The Wolfenden Report, enlightened in its recommendation, that homosexual acts of whatever kind, voluntarily committed between those over 21 years of age, be considered in the same way as heterosexual acts, yet endorses the penalty of life imprisonment for sodomy with a boy under sixteen.

Live and Let Live is a poignant witness of how much unreasoned passion the problems of homosexuality and prostitution can engender on either side. The book adds but little to the objective analysis of these problems.

IACO GILDSTON, M.D.
New York, N. Y.

AN APPRAISAL OF ELECTROENCEPHALOGRAPHY IN RELATION TO PSYCHOLOGY. By A. C. Mundy-Castle. (Monograph Supplement No. 2, Journal of the National Institute for Personnel Research, South African Council for Scientific and Industrial Research, May 1958.)

This is, as the author suggests, a rather critical appraisal of electroencephalography in psychological research rather than a review of the EEG findings in psychiatry. However, of necessity, the author touches on at least most of the important papers dealing with the latter subject as is evidenced by the 444 references. In this monograph there is a successful attempt to develop in an orderly fashion the relation of personality to EEG, then the neurophysiological aspects of the EEG and finally, the psychological implications of these particular neurophysiological findings. It is made evident that the EEG as a neurophysiological tool has much to offer in psychological research particularly in regard to such topics as central excitability, arousal, temperament, learning, and habituation.

Though interest in the EEG as a technique in psychological research dates back about 30 years and to Hans Berger, there has been a considerable increase in the productivity of such research in the last 10 years. The results of what now has been discovered certainly foretell of considerable advancement in our useful knowledge of the basic mechanisms underlying psychological processes. This short monograph is highly recommended to psychiatrists of all learning for though it revolves about the use of EEG it is not focused on clinical electroencephalography *per se* but rather correlates quite well much information concerning basic and therefore important aspects in psychology and hence in psychiatry.

W. J. FRIEDLANDER, M.D.,
Boston 30, Mass.

THE PSYCHOLOGY OF PERSONALITY. Edited by J. L. McCary. (New York: Grove Press Inc., 1956, pp. 383. \$1.95.)

This book presents 6 modern approaches to the study of personality which vary from small footpaths to large avenues. The chapters, perhaps by design of the editor, improve as the book progresses. In the first chapter, Dr. Leopold Bellak grapples unsuccessfully with the task of presenting a review of psychoanalytic theory which will not seem ludicrously out of date. Psychoanalysts will always suffer from Freud's insistence that others accept his system altogether or not at all. We could use his great contributions better if he and his followers had contented themselves with developing an approach, as the title of this book suggests, rather than a system. Psychoanalysts have made larger claims than any other group of psychologists or psychiatrists to a comprehensive and accurate view of human behavior. Yet paradoxically they have done almost nothing themselves to validate their theories in an acceptably scientific manner. We can count on the fingers of one hand the psychoanalysts who have themselves conducted serious investigations such as Fisher's studies of perception and dreams. If a modern exponent of psychoanalysis adheres to Freudian doctrine, what he says seems archaic; if he flexibly involves himself with other contributions he seems then to write less and less about psychoanalysis.

Dr. Raymond Cattell contributes a chapter chiefly devoted to a review of his work on the factor analysis of behavioral traits. The fruit in Dr. Cattell's vineyard seems to ripen slowly. His chapter should interest theoreticians of personality, but offers little to the clinician. Dr. George S. Klein reviews the contributions

of studies of perception to the theory of personality. He summarizes some rather recondite, although potentially significant investigations. Unfortunately, he penalizes himself and his readers with bad writing. I will put in the pillory one particularly grotesque example of this to remind scientists that they have an obligation to communicate clearly as well as to think clearly. If they cannot do one, how can we know they can do the other? The following sentence actually occurred: "The upshot is a curious situation in which vigorous points of view, often solidly enough anchored to measurable phenomena, move in parallel fashion over the same terrain, each encouraged by the seeming success of its tools to go its own way with little concern for others."

Dr. Margaret Mead next describes contributions of anthropology to the study of personality. In the next chapter, Dr. Nevitt Sanford reviews the approach to personality of those studies which contributed to the book, *The Authoritarian Personality*, of which Dr. Sanford was himself a co-author. Dr. Sanford and his colleagues combined certain psychoanalytic theories with techniques of sociology and clinical psychology in a clever study of behavior along the dimension of independence vs. submission and tyranny, the last two conceived as expressing opposite sides of the same coin. Dr. David McClelland concludes the book with an ostensible review of what the other contributors have said. Fortunately, he includes in this a summary of some of his own contributions to studies of traits and motives. He writes thoughtfully about the ways in which later experiences modify the effects of earlier experiences and why they cannot always easily modify such effects.

This book exemplifies an increasing number of published reports of symposia in our subject. I think many of them, including this one, fall between two levels of writing. The contributors have insufficient space to furnish in detail the evidence for many of their statements; this can irritate the informed reader who will want to study the original reports of investigations. On the other hand, they write at a level of sophistication too advanced for the novice; and this may irritate the busy clinician who wants, unwisely perhaps, something he can immediately apply in his everyday work. Should psychiatrists read this book? Certainly not if they hope to reform their practices by instant application of these "approaches." Yet the psychiatrist who wishes to learn about work on the growing edge of the psychology of personality may inform himself about much of such work by reading

this book, especially the chapters by Drs. Sanford and McClelland.

School of Medicine.

HEREDITY AND EVOLUTION IN HUMAN POPULATIONS. By L. C. Dunn. (Cambridge, Mass.: Harvard University Press, 1959, pp. 157. \$3.50.)

One of the happiest marriages in the history of science may be likened to that between mathematics and physics. In our own time it is the marriage between genetics and evolutionary theory. In the present small and very readable volume Professor Dunn shows why the union is so like a continuous honeymoon. Genetics, the science of heredity is to evolutionary theory as nuclear physics is to atomic theory. Genetics supplies the answer to the question: What are the raw materials upon which evolution works? The answer that genetics supplies is: The genotype, that is, the genetic constitution of the organism as contrasted with its manifested characteristics (the phenotype). Genes forming the genotype mutate, and mutations are part of this raw material upon which natural selection works in influencing the differential fertility of the different genotypes. This year, 1959, we are celebrating the demonstration by Darwin of the high probability of natural selection. What Darwin did not have available to him was Mendel's discovery of particulate inheritance. Inheritance and evolution are a matter of population, in that genes are exchanged in the gene pool of a population. Hence, the understanding of what transpires genetically in populations is of the first importance for an understanding of the nature of the evolutionary process. It is precisely this that Professor Dunn is concerned to make clear in this admirable little volume which may be cordially recommended to all classes of readers.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE PHENOMENOLOGICAL PROBLEM. Edited by Alfred E. Kuenzli. (New York: Harper & Brothers, 1959, pp. 321. \$4.50.)

This is a collection of 14 articles which have appeared in 10 different journals between 1939 and 1957. It is the hope of the editor that "this collection will be regarded as truly a set of 'working papers,' not just a book of readings." Designed for the younger men in the field, it is meant to stimulate discussion in upper-level seminars, particularly for majors

in clinical and social psychology and should clarify what is meant by a phenomenological emphasis in modern psychology as well as achieving a greater degree of integration of knowledge within the fields of clinical and social psychology. The contributors are Hadley Cantril, Arthur W. Combs, Lawrence K. Frank, Richard Jessor, Abraham S. Luchins, Robert B. MacLeod, Theodore M. Newcomb, Victor Raimy, Carl R. Rogers, Saul Rosenzweig, M. Brewster Smith, Donald Snygg and Daniel W. Soper.

A.G.

PSYCHOLOGICAL PROBLEMS IN MENTAL DEFICIENCY. 3rd Ed. By *Seymour B. Sarason*. (New York: Harper and Brothers, 1959, pp. 678. \$6.50.)

Ten years ago S. B. Sarason brought together, for the first time, about 350 widely scattered psychological articles and monographs on the non-biological dimensions of mental retardation. Dr. Sarason has once more served by appending the last decade of pertinent research to his two previous editions. The third edition reports and evaluates the produce of more than 650 social science writers on mental retardation. The result is an exhaustive source book.

All 3 editions treat chiefly of the impact of cultural and socio-economic forces upon general intelligence, psychometric performance, and academic proficiency with the retarded. The summary evidence courts the view that the brighter garden-variety mental defective is etiologically derived from these several variables. Such a thesis invites fresh momentum towards *early* educational therapy, or indeed, for *early* case work intervention with the retarded family. The moron is not, apparently, as intrinsic a part of mankind as the currently nebulous genetic view of human intelligence pretends.

Part I of the book is identical to all prior editions. As well, the new Part II of the third edition is already well circulated as *Mental Subnormality* (Basic Books, 1958), as a monograph supplement of the *American Journal of Mental Deficiency* (1958), and as a *Genetic Psychology Monograph* (1958).

Moreover, Sarason has made no effort to integrate the recent research with the older. In a burst of candor he excuses this shortcoming on the dual bases of lack of enthusiasm and of time. More justly, it might be remarked that the psychological research into intellectual subnormality has grown too vast and too varied to be compressed within a single book. Instead,

the field now requires more specialized manuals of assessment practices, training and treatment techniques, and lastly, an evaluation in depth of the implications of subcultural research for current notions of intellectual development and learning theory.

DAVID GIBSON,
University of Toronto.

LONG-TERM ILLNESS. Management of the Chronically Ill Patient. Edited by *Michael G. Wohl*. (Philadelphia: W. B. Saunders Co., pp. 748, 1959. \$17.00.)

Part I deals with general principles in the management of chronically ill patients. Included are discussions of the best hospital settings for the chronically ill, home care, principles and organization of facilities for rehabilitation, and psychological problems associated with long-term illness. Part II contains the therapy of specific diseases. Chronic psychoses and severe neuroses are apparently not considered to be long-term illnesses. For example schizophrenia, perhaps the most important cause of prolonged disability, is not discussed. One finds no reference to the management of either the hysterical patient or the paranoid workman claiming compensation, both familiar types in departments of rehabilitation.

Most of the chapters reflect the thinking of experienced clinicians who know both the limitations and the potential benefits of drugs and surgical measures in treating the various chronic illnesses. Throughout, the importance of an optimistic, kindly and reassuring attitude on the part of the medical team is stressed. Special pleading appears in a few places. We find broad-spectrum antibiotics advocated in the treatment of rheumatoid arthritis. The rationale consists of a possibility that bacteria, perhaps of the pleuropneumonia-like group, may be the cause of the disease. We learn that evaluation of the long-term effectiveness of the antibiotics is incomplete. Surely it is wrong to advocate such measures unless a very critical evaluation has been completed.

Generally speaking the book can be recommended. Many physicians will find it useful for reference. Hospital psychiatrists have here a valuable compendium of the treatment of chronic illness. The book deserves to be in hospital libraries. In planning a second edition it might be well to take account also of chronic mental disorders.

University of Toronto.

A DESCRIPTIVE DIRECTORY OF PSYCHIATRIC TRAINING IN THE UNITED STATES AND CANADA, 1960. 3rd Ed. Compiled under the Auspices of the Committee on Medical Education of the American Psychiatric Association. (1700 18th St., N. W., Washington 9, D. C., pp. 116. \$3.00.)

The Directory is comprised of three sections. Section I contains full information for applicants for certification in Psychiatry and Neurology, and for applicants for certification in Child Psychiatry. Section II consists of descriptions of residency training programs in psychiatry, approved by the Council on Medical Education and hospitals of the American Medical Association and the American Board of Psychiatry and Neurology. Section III lists the Canadian hospitals approved for advanced graduate psychiatric training, by the Royal College of Physicians and Surgeons of Canada.

Copies of the Directory can be obtained from the Washington Office of the APA, 1700 Eighteenth St., N. W., Washington 9, D. C.

S.L.

HANDBOOK OF NEUROLOGICAL DIAGNOSTIC METHODS. Edited by *Fletcher McDowell, M.D.*, and *Harold G. Wolff, M.D.* (Baltimore: Williams and Wilkins Co., pp. 201, 1960. \$4.50.)

This handbook has been developed over the past 28 years by the members of the Neurological Division of Cornell University Medical College. The present manual represents the most recent revision.

The first portion describes a method of inquiry to elicit evidence of gross structural disorders of the nervous system as well as disturbances involving personality and life adjustment. There follows a detailed account of the neurological examination. The second part consists of descriptions of the various techniques used in carrying out 17 special procedures required for neurological investigation together with their interpretation. Worthy of particular mention are the chapters on visual fields, examination of an aphasic patient, cystometry, electroencephalography, electrodiagnostic procedures and lumbar puncture, the latter including a table describing the cerebrospinal fluid findings in many diseases. In the final portion of the book various neurological emergencies such as coma, acute head injuries, status epilepticus, ventilatory failure, etc., are considered together with their management. The last chapter consists of a questionnaire for students on neuroanatomy, neurophysiology and clinical neurology. The ability to answer

these questions correctly is regarded as the minimum of information essential to an intelligent understanding of diseases of the nervous system.

The handbook is clearly designed for medical students in their clinical years but it should be of value also to medical practitioners for quick reference. It reflects the mature judgment of a group of outstanding neurologists, expressed in a clear, concise manner. It can be highly recommended as an up-to-date and balanced exposition of modern diagnostic methods in neurology and its size will permit a student to carry it with him for use while working on the wards.

HERBERT H. HYLAND, M.D.,
Toronto, Ont.

KLINISCHE PSYTHOPATHOLOGIE. 5th Ed. By *Kurt Schneider.* (Stuttgart: Georg Thieme Verlag, pp. 166, 1959.)

Kurt Schneider's clinical psychopathology is, in his own words, "psychopathological symptomatology and diagnostics." It is based on the "empirical dualism" distinguishing (a) abnormal personalities and their experiential reactions from (b) sequelae of diseases and malformations. (c) Can be subdivided into a somatological (or etiological) and a psychological (or symptomatological) column. Clinical and psychopathological data and discussions are given on a variety of topics. A particularly interesting chapter deals with cyclothymia and schizophrenia. This chapter contains, among other considerations, a few pages on delusion which belong to the very best this reviewer read for years on this knot of problems. This fifth edition of a remarkable book is written with commendable selfdiscipline by an author of highest renown, wide experience and profound erudition. It certainly fully deserves its success.

EUGEN KAHN, M.D.,
Houston, Tex.

IRRWEGE DER MENSCHLICHEN GESELLSCHAFT (ERRANT WAYS OF HUMAN SOCIETY). By *Julius Bauer.* (Liestal: Ars Medici Lüdin AG, pp. 151, 1959.)

The author of this book on "Errant Ways of Human Society" is an unusually capable, well known physician, professor and research worker. The many insufficiencies and deficiencies of Western Culture weighed so heavily on him that he just had to write this medical-psychological critique on them. It is earnestly hoped that he is feeling better about it now. He was bitter about the herd that runs after the

leader; he regretted the "infantilism" and the stupidity of ever so many citizens caught in the web of conformism. Unless the individual would be given a chance to mature and to do some thinking of his own, the professor had slim hope for the development of a "mentally mature society" with an appropriate, well organized democracy.

EUGEN KAHN, M.D.,
Baylor University,
Houston, Tex.

THE EFFECT OF PHARMACOLOGIC AGENTS ON THE NERVOUS SYSTEM. Proceedings of the Association for Research in Nervous and Mental Disease. Vol. 37. Edited By *Francis J. Braceland*. (Baltimore: Williams and Wilkins Co., 1959, pp. 450. \$13.50.)

In the preface it is stated that this book contains "the chemical experience, considered evaluations and aspects of the research activity of many outstanding investigators, as well as reviews of the literature." Forty authors, in 26 papers, discuss methods of evaluating drugs which affect the nervous system, the pharmacology and clinical use of such drugs, and some of the underlying biochemical mechanisms which influence mental health and disease. No useful purpose is served by itemizing the contents or the contributing authors.

This collection of papers covers a wide range of subjects and reflects the immediate interest of many investigative groups in neuropharmacological subjects. For the investigator, clinical or experimental, it is of immediate and lasting value. Several of the papers should be of practical import to the practising psychiatrist or internist, and to those entering these fields the papers as a group will interest, instruct and stimulate.

E. A. SELLERS, M.D.
University of Toronto.

DIE CEREBRALE GEFÄSS-SKLEROSE. By *Hans E. Kehrer*. (Stuttgart: Georg Thieme, pp. 238, 17 ill., 4 tables, 1959. \$6.70.)

This handy little volume treats the diagnosis, treatment and social aspects of cerebrovascular sclerosis. It begins with descriptions of the objective signs of the apoplectic stroke

and the periods of restitution. The constitutional types are considered and various forms of cerebral pathologies presented. Of the subjective signs are described: vertigo, aural noises, headaches, trigeminal neuralgia, glossodynia, sleep disturbances, etc.

Of the psychiatric symptoms involved, the author discusses in detail: torpidity, irritability, personality changes, weariness, lack of concentration and judgment, diminution of affect, memory and thinking capacity, disorientation, fabrication, depression and paranoid tendencies.

He points out the areas where arteriosclerosis may be detected by tactile investigation, retinal examination and tests such as digital compression of the carotid. He then discusses the vascular calcifications made evident through roentgenology, angiography, encephalography and examination of the cerebro-spinal fluid.

Special chapters are devoted to the pathogenesis of cerebro-vascular sclerosis and to the various therapies. Among the latter are considered: venesection, hemostyptics, stellatum anesthesia, cortisone, anticoagulants and vasodilators. In trigeminal neuralgia, surgery is suggested only if non-surgical remedies have failed. He advises to try small doses of insulin, hydantoine, vitamin B and ergotamine.

Vertigo and nausea are relieved by hydergin taken sublingually and by priscophen. Ear noises are treated with theomagnal and histamine preparations. For ocular scotomata Ronicol compositum is used. For Parkinsonianism, akineton is suggested and the feeling of fatigue and weakness may be mitigated by the antihistaminic soventol, which may, however, become habit-forming.

The relief of psychic symptoms is described in a special chapter that contains some original ideas. The "sociological involvements" refer to the application of civil and criminal laws in the activities of cerebral arteriosclerotics.

In the last chapter the author points out that the overwhelming majority of known celebrities in all walks of life, from antiquity down to modern times, retained all their intellectual prowess and emotional control to the very last, irrespective of their age. This disproves the accepted assumption that senility is the inevitable sequence to senium.

New York, N. Y.

THE ADOLF MEYER RESEARCH LECTURE

THE STUDY OF DEFECT¹

PROFESSOR SIR AUBREY LEWIS, M.D., F.R.C.P.²

I believe I am the first Adolf Meyer Lecturer to have enjoyed the privilege of working at the Phipps Clinic in the days when Dr. Meyer was its head. It was therefore with exceptional pleasure that I learnt I was to have this opportunity of recording my personal debt to him. Tributes to the outstanding man in whose name this Lecture has been established have taken many forms, and American psychiatrists know better than we who came to Hopkins from abroad, what his services have been to psychiatry in this continent. But it is right for us who carried back to our own countries what we had learnt, to say what we owe him: the example of his integrity—his moral and intellectual integrity—and his conception of the humane aims of our specialty. These exercised a force upon his pupils whose effect can still be discerned in the psychiatric developments of Great Britain and some of the Scandinavian countries. No doubt it is a mistake to look around in one's middle age and decide that in comparison with the great men under whom we served our apprenticeship we are a lesser breed of epigoni, busy in dotting i's and crossing t's: it would, however, be no mistake to say that for the progress we have seen in psychiatry during the last quarter century we owe much to the labours of predecessors, very notable among them Adolf Meyer, teacher and exemplar.

I have chosen to speak of the study of defect. This may seem a paradoxical choice, since of all the wide issues in psychiatry mental defect is the one which Dr. Meyer least considered in his oral teaching and his writings. In his Salmon Lectures (32) he acknowledged the relative lack of plasticity and modifiability in defectives, and the pas-

sage might be taken to suggest that because of his melioristic passion, the intractability of this group of constitutional weaknesses put them outside the scope of his concentrated thought and effort. Such an inference would be, I think, mistaken. Dr. Meyer was distressed by the common attitude of superiority and even contempt towards the mentally defective: he tried to counter it by emphasizing "that there are perfectly good and useful imbeciles and that it is the use, and not only the quantity of the assets which decides human desirability" (31). But lacking clinical access and experience in these conditions, and having so much work to his hand in other areas of psychiatry, it is not surprising that he said and wrote very little about the intellectually handicapped.

The intellectually handicapped—in using such a phrase I am perhaps begging a question? At home I should almost certainly be told that I am, for this is a contentious issue with us. Because of it mental defect has become a murky concept. The most recent and outspoken inquirer (48) into this vexed matter concludes that

the urge to get away from purely intellectual concepts of mental deficiency and to substitute the criterion of social competence, has thus left us with a situation which is fantastically complicated—or perhaps "muddled" would be a better word.

I shall be returning to this cardinal issue: I mention it now, as a reminder—at any rate for us in England—of the fuzzy outlines and unsteady basis of the object of our studies in retardation, or defect (as I think we may still call it).

It has been until lately a neglected branch of psychiatry. But in research this is now happily untrue. The rate at which fresh knowledge about mental defect has been accumulated in the last 20 years contrasts strangely with the slowness with which pub-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² The Institute of Psychiatry, The Maudsley Hospital, Denmark Hill, London, S.E. 5, Eng.

lic authorities and doctors have given up regarding it as an Ugly Duckling. In few countries does the care of defectives receive the administrative and financial support that is accorded to psychotic patients—extramural facilities for them are weaker than those offered to the neurotic who seeks help in outpatient departments and day hospitals; and, most disconcerting of all, the bulk of psychiatrists do not regard this branch of clinical work as lively and rewarding.

Yet its notable recent triumphs are surely the prelude to a wide advance. The doors are opening fast. At least 5 distinct metabolic anomalies have been detected, so that possible ways appear of aborting their ill effects on mental growth: the genetic peculiarity of mongolism has been disclosed in the extra chromosome produced, we may suppose, by non-disjunction; challenging evidence has accumulated on maternal conditions during early pregnancy which may retard a child's mental development; the capacity of imbeciles to learn has been found greater than we thought. These are advances, fit for application to treatment and prevention, which are as considerable as any made in the study of other forms of mental disability during the same period. Professor Böök(5) says that in the field of mental deficiency we can see some of the most brilliant contributions of genetics to psychiatry; that statement might be extended, I believe, to cover the contributions of biochemistry and perhaps of psychology also. In spite of this arresting efflorescence of research in mental deficiency, it remains the branch of psychiatry that seems least attractive to our recruits. For a vacant post in the mental deficiency hospitals competition is less keen than for posts of the same standing in the other mental health services. Yet the prestige of any subject commonly rises when it is known to be advancing in basic knowledge that can be applied to human affairs. It may be objected that though this sort of prestige impresses informed on-lookers and attracts research workers it does not move doctors to take up the practice of a special branch of medicine. This I doubt: while recognising, of course, that many other factors besides impressive scientific advance determine the choice of a particular

career in our profession. Professor Merton's investigation(30) showed that the process begins early. The recent study by Professor Pasamanick and Dr. Rettig(39) has confirmed that in the eyes of medical students psychiatry still ranks low among the specialties; and one may suspect that if subdivisions of psychiatry had been explored, work in the mental deficiency services would have been found near the bottom of the list.

Is this poverty of esteem because the study of defect is unimportant to modern society? Far from it. In England and Wales—to take the statistics best known to me—the expectancy of admission to a mental deficiency hospital is four for every thousand male births, and three per thousand female births: over a quarter of all the beds for mental disorder are reserved for mental defectives; besides the occupants of these 58,000 beds in mental deficiency hospitals, there were nearly 80,000 ascertained defectives receiving community care from local health authorities in 1955. In spite of many causes for divergence in prevalence estimates, there is substantial agreement between surveys carried out at different times and in different places during this century which indicate a prevalence rate of between 0.8% and 1.0% of population, or 3% to 3.5% of the population under the age of 18, exhibiting varying forms or degrees of defect. This figure proclaims the rough extent of the aggregate personal misfortunes, the waste and the socio-economic handicaps which widespread mental defect implies for a civilized community. It is true that these are crude statements. Defect is not a biological entity, or indeed a psychological or pathological entity, but rather a congeries of morbid conditions. Its prevalence is not an absolute, but a conditional estimate. The cultural values and attitudes of a society have much to do with its recognition and may determine how heavy will be the economic and social burden it creates. Moreover, here kindness may be cruel, and efficient provision a hardship: for in a wealthy, humane, highly organised society people who are poorly endowed may be set aside and debarred from living a normal life, so that they cannot contribute their self-respecting mite to the common

stock or fulfill their side of the social contract, whereas in a ruder, less exacting society they might be integrated into the life of the community and be indistinguishable from the common run of its members. And the extent of the liability is mounting: the social and medical advances which permit mongols and other handicapped children to survive, lead to an appreciable increase in the prevalence of defect: a fourfold increase over the last 30 years in the prevalence of mongols in the population of children aged 10 years, as Carter(7) has recently shown. Such considerations reinforce the argument that here in defect we have an enormous social and medical issue—or rather network of issues. They underline the disturbing paradox: mental defect is a challenging, insistent, promising branch of psychiatry, yet psychiatrists are not, on the whole, drawn towards it.

It is all the stranger when we consider that the study of defect promises to throw light not only on its own path but on some of the byways of the rest of psychiatry—byways so often traversed that they have become ruts leading into bogs. There are important and popular divisions of psychiatry in which the law of diminishing returns is painfully evident, so that there is much cry and little wool. This cannot be said of the study of defect at the present time, nor of its potential relevance to cruxes that puzzle psychiatrists generally. Now that the ice has broken here in the streams of biological, social and psychological research, our understanding of mental illnesses stands to profit from advances in knowledge of the pathology—psychopathology and somatic pathology alike—of mental defect. Perhaps the paradox I have been dwelling on is only a matter of time-lag. Among psychiatrists in England at any rate there has been, I believe, a perceptible quickening of interest during the last two or three years in the practice as well as the study of mental deficiency: it can be attributed to their awareness of the scientific stirring in the subject, and its closeness to other psychiatric issues of moment.

The concept of defect has, of course, long been based on a simple dichotomy, that many would say has now served its turn. It was summed up by Esquirol(10) in an epi-

gram—"The dement is a man deprived of the possessions he once enjoyed, he is a rich man who has become poor. But the defective has been penniless and wretched all his life." Esquirol—who said also "Defect is not a disease, it is a condition"—was herein making a distinction that had been firmly established in jurisprudence. The common law of England, from the 13th century, drew a line between the "natural fool," witless from birth, and the lunatic who "hath had understanding but by disease, grief, or other accident, hath lost the use of his reason." Similarly in the early Brehon Laws of Ireland. It is an obvious way of dividing those who have never been, from those who have ceased to be, mentally normal. Yet this commonsense differentiation took a long while to achieve clinical sanction. At the end of the 18th century the medical distinction between dementia and defect took a long while to achieve clinical sanction. At the end of the 18th century the medical distinction between dementia and defect was blurred, as we see very plainly in the writings of such leaders as Philippe Pinel and Johann Christian Reil:

Insanity in one of these forms can go through a sort of transformation, emerging in another form, so that one sees melancholics pass into mania, some manic patients fall into dementia or idiocy, and sometimes even some idiots pass into a temporary attack of mania and then fully recover the use of their reason (Pinel) (41).

Such being the jumble, Esquirol was rendering some service to clear thought by asserting the distinction he did, with sharp and authoritative precision. But it is significant of the whirligig on which our thinking about these matters seems to turn, that we are now veering back in some respects to the position which had been assumed by Esquirol's predecessors, and which seemed to have been abandoned more than a hundred years ago. A few months ago a Committee of the Group for the Advancement of Psychiatry, in their brochure on basic considerations in mental retardation, wrote(15):

Historically the concept developed that deviant children could be classified accurately into clear-cut categories such as the psychotic, the neurotic, those with character problems, and

the mentally deficient. More recent experience has underscored the difficulties inherent in differential diagnosis. In a substantial number of cases the diagnostic term attached to a given patient depends upon the orientation of the examiner rather than upon the presenting symptomatology or developmental history of the patient.

Such subjectivism is an indictment of our discipline (if we may continue to call it a discipline, after that), but it shows the way the wind is blowing.

Classification is usually a jejune theme. In this instance it has the value of a signpost, betokening changes in the direction of our thought about the nature of defect. The latest swing is expressed in the 1957 report of our Royal Commission(42):

The basis for this (the traditional) distinction between the mentally ill and the mentally defective is practical rather than scientific. Broadly speaking, people who develop a mental illness in adult life and people who have been mentally retarded since birth or childhood need and receive different forms of care and treatment. On the other hand, the term "mental defectiveness" as well as the term "mental illness" covers a wide range of mental conditions, and there is a body of opinion which considers that it would be more suitable to treat some forms of mental deficiency in the same hospitals as the milder forms of mental illness than to accommodate all types of mentally defective patients together in one hospital. It is also a fact that some diseases which affect the brain, at whatever age they occur, result in a mental condition similar to that of a person whose mind has never fully developed, and general degeneration of the mental faculties in adult life sometimes has a similar result. One of the questions on which opinions differ widely, is whether the term "mentally defective" should be confined to people who are subnormal in intelligence, or whether it should also be applied, as it sometimes is at present, to some whose intelligence is normal, being near or even above average, but who show serious lack of maturity in other aspects of their personality.

After lengthy discussion of the question the members of the Royal Commission concluded that the general class "mental disorder" should include disability from defect as well as illness; and in the Mental Health Act which became law last year their

recommendation was adopted. Of course neither Royal Commissions nor Acts of Parliament can make us use for medical purposes categories which we do not think useful and apt; but the statutory changes were in fact the response of legislators to a strong trend of informed medical opinion. The implications of this trend reach far, and I shall return to it.

The revolutions of opinion about how defect should be classified and treated derive from historical influences more extraneous to medicine than is commonly supposed. Certain of these deserve closer regard.

In the first phase social issues—such as criminal responsibility, and capacity to control one's possessions—dominated systematic consideration of the nature of defect. Men stressed its kinship to the limited capacity of children to reason, to judge moral or intellectual issues, and to act appropriately. Hence came feudal claims to wardship of the land of a "natural fool," "purus idiota," and the definition of

an idiote or a natural foole is he who notwithstanding he bee of lawfull age, yet he is so witless that hee can not number to twentie, nor can he tell what age he is of, nor knoweth he who is his father, or mother, nor is able to answer any such easie question.

At the same time influences of an older date caused defectives to be credited with guileless virtue, so that "innocent" and "crétin" (chrétien) were considered appropriate terms for them.

As we move through the centuries towards our own time, philosophers have more and more to do with the matter. Vives, the pupil of Erasmus, developed the principle that in education the process of learning is determined not only by the subject matter to be learnt but by the nature of the learning mind. And, concerned as he therefore was to adapt methods of instruction to the peculiar needs of the learner, he became a pioneer in urging the special requirements of the mentally defective and the deaf. A century later came Locke, insisting that all knowledge derives from experience, by way of sensation and reflection, *i.e.* introspection—a view half accepted by Condillac, with consequences that are still discernible in our methods of treating de-

fect. Condillac, in his famous model or myth of the animate statue endowed only with one modality of sensation, illustrated his belief that from sensations all the mental operations, including desire and abstract thought, are genetically developed: hence it followed that anyone who would educate children who are handicapped from their earliest years must foster a dual process, training them in observation and training them in reasoning.

Everybody knows how these views, and probably those of Helvetius, determined the persevering experiment by Itard 150 years ago which, misguided though it was in aim, put an end to the long era of hopelessness and neglect for the imbecile. All that has since been done, and is still being done, for the education of the mentally defective harks back to that patient application of 18th century philosophy.

In the 19th century the extraneous forces came not from philosophy but from biology: and within medicine, from morbid anatomy.

The biological mold into which current knowledge about defectives was poured was at first largely anthropological, in the spirit of Blumenbach and Prichard—and of course Gall. Interest in the size and shape of skull became intense. Medical writings on defect in the first half of the 19th century are cluttered with cranial measurements. Esquirol devotes six or seven pages of his textbook to considering the value of such measurements; Griesinger likewise. But little was gleaned from all this craniometry. Thomas Fuller had put the matter in a nutshell—"their heads (those of naturals) sometimes so little, that there is no room for wit; sometimes so long, that there is no wit for so much room."

Another illegitimate offspring of biology and anthropology was the long-lasting conception of mental defect as the last or the "atavistic" stage in the degeneracy of a stock; it was in its heyday when propounded by Morel, it passed into its decline with Langdon Down and, last of all, Cruikshank: and was deeply involved in the pedigree-haunted terrors of those who told us about the Jukes and the Kallikaks.

In this century the dominant influences upon defect have come from more dispersed fields of knowledge—from metabolic studies,

from epidemiology, genetics, and—in grateful mutuality—from psychology, which owes to mental defect the incalculable impetus given by Binet's brilliant development of mental tests between 1904 and 1911 (2,3,4). In our time investigation into mental defect has been responsive—sometimes weakly, sometimes strongly—to every wind that blows through medicine: witness the sizeable output of papers on the effect of "tranquilizing" drugs upon defectives, and the little series of reports a few years ago on what prefrontal leucotomy and hemispherectomy could do for some disturbed imbeciles. The Zeitgeist seems to have been quite busy, fixing the advances, and ensuring the periods of stagnation, in this branch of psychiatry.

There is, however, one tributary to the stream of progress that has received, I think, too little attention. For the last hundred and fifty years or more it has flowed powerfully though intermittently.

This is the study of language, and particularly its application to the work of teaching deaf children to speak. There are several curious themes which intersect the mesh of this story. I do not want to go too far back, so I shall remind you only of Lord Monboddo, the forerunner of Darwin. Lord Monboddo(6) maintained that speech is not performed "naturally," but is acquired by custom and exercise, and in support of this quoted the "wild men who had been reported, from the 14th century onwards"—

I say in the first place that of all those savages which have been caught in different parts of Europe, not one had the use of speech, though they had all the organs of pronunciation such as we have them, and the understanding of a man, at least as much as was possible when it is considered that their minds were not cultivated by any kind of conversation or intercourse with their own species . . . One of these was caught in the woods of Hanover as late as the reign of George I and for anything I know is yet alive . . . He was a man in mind as well as body, as I have been informed by a person who lived for a considerable time in the neighbourhood of a farmer's house where he was kept and had an opportunity of seeing him almost every day, not an idiot, as he has been represented by some who cannot make allowance for the difference that education makes upon men's minds; yet he was not only

mute when first caught, but he never learned to speak.

Here, in 1774, we have a topic familiar in the earlier history of defect—can a “natural” or feral man be educated; we have also the prelude to the hotly argued debate as to whether these wild men are mute and brutish because they have been brought up away from human kind, or because they have congenital mental defect. You may be wondering whether Monboddo borrowed his ideas from the French philosophers then busy with such matters. I think not. He tells us that he developed his opinions without knowledge of Condillac’s views (though he later read an extract from the *Essai sur l’origine des connaissances humaines*).

Lord Monboddo clinched his argument about the origin of speech by adducing a special case.

What puts the matter out of all doubt, in my apprehension, is the case of deaf persons among us. And their case deserves to be the more attentively considered, that they are nearly in the condition in which we suppose men to have been in the natural state. For, like them, they have the organs of pronunciation; and, like them too, they have inarticulate cries, by which they express their wants and desires. They have likewise, by constant intercourse with men who have the use of reason, and who converse with them in their way, acquired the habit of forming ideas; which we must also suppose the savage to have acquired, tho’ with infinitely more labour, before he could have a language to express them. They want therefore nothing in order to speak, but instruction or example, which the savages who invented the first languages likewise wanted. In this situation, do they invent a language when they come to perfect age, as it is supposed we all should do if we had not learnt one in our infancy? Or do they ever come to speak during their whole lives? The fact most certainly is, that they never do; but continue to communicate their thoughts by looks and gestures, which we call signs, unless they be taught to articulate by an art lately invented.

Monboddo then describes the methods used by the Abbé de l’Epée in Paris and by Braidwood in Edinburgh, and continues:

If it had not been for this new-invented art of teaching deaf persons to speak, hardly anybody would have believed that the material or mechanical part of language was learned with so much difficulty. But if we would get an Orang Outang, or a mute savage such as he above-mentioned who was caught in the woods of Hanover, and would take the same pains to teach him to think that Mr. Braidwood takes to teach his scholars to speak, we should soon be convinced that the formal part of language was as difficult to be learned as the material. For my own part, I am fully persuaded that the minds of men laboured as much at first, when they formed abstract ideas, as their organs of pronunciation did when they formed articulate sounds; and till the mind be stored with ideas, it is a perfect void, and in a kind of lethargy, out of which it is roused only by external objects of sense, or calls of appetite from within. It was this want of ideas which made the Hanoverian savage pass, in the opinion of many, for an idiot.

The parallel here with Itard’s (19) reasoning in the famous case of Victor is obvious: the education of the wild or natural man is to be modelled on that of the deaf-mute. For Monboddo the exponent of how to teach the deaf is the Abbé de l’Epée; for Itard, 30 years later, it is de l’Epée’s pupil and successor, the Abbé Sicard. There were, of course, conspicuous differences between Itard and Monboddo; one was a young doctor of 25, the other an elderly judge, a busy Lord of Session at Edinburgh: and whereas one was enthusiastically occupied day by day with treating deaf children at the Institution Nationale des Sourds-et-Muets, the other was able only to speculate about them and about others deprived of a normal upbringing. But the line of thought was the same, and it brought lasting benefits to the defective.

Itard’s example fired Séguin, who never faltered in his admiration for the man and his achievement. And like Itard—possibly because he had been Itard’s pupil—he looked back in his efforts for the defective to the principles which underlay the successful education of deaf-mutes. But it was not to the principles of de l’Epée and Sicard, but to those of their brilliant rival, Jacob Rodriguez Pereira, that he turned for guidance. Whereas de l’Epée had been content to teach the deaf to communicate

by signs and finger-spelling, Pereira taught them to speak. Séguin(43) drew an analogy between Pereira's basic principles and those which had enabled Séguin himself, as he believed, to solve the problem of treating defect.

I am not unaware that the problem of educating deaf-mutes was attacked and even solved in the last century from a wider standpoint, that of Pereira, which is strikingly analogous to that which I have used to solve the problem of treating mental defect.

This analogy bore practical fruits in many countries. When Séguin came to this country it was to Dr. Samuel G. Howe, an expert in the treatment of the deaf and the blind, as well as of the feeble-minded, that he first went. In Germany, at the same time, Dr. Saegert, the head of the Asylum for Deaf-Mutes in Berlin, established his school for defectives (1842). Earlier in the century Albrecht Vering in Münster, Guggenmoos in Salzburg, K. F. Kern in Möckern, and Katenkamp in Oldenburg had conducted the education of mentally defective, deaf and blind children in the same schools, on the same broad principles.

There was, it is clear, a powerful and significant transfer from the theory and practice of educating the congenitally deaf, to the training of the mentally defective. This derived from recognition of the cardinal role that language and speech play in mental activity. Esquirol said that

what determines the peculiar character of the different varieties of defect is the use of language, that essential attribute of man, given him to express his thought : it is the feature most clearly related to intellectual capacity in defectives.

Fifty years ago Binet and Simon endorsed Esquirol's view :

So one can distinguish the patients according to their ability to speak or to learn to read, because these are not inherent faculties but practical attainments which depend on the energy and level of certain faculties : and that is all measurable.

The issue still has contemporary importance. In current research, when we talk of

problem-solving and thinking, we are forced to consider how words enter into the formation of concepts, and facilitate generalizations. And since even the simple operations which imbeciles can carry out, may entail the solving of a problem, we have to regard closely the defective's way of attaining concepts, and of using verbal generalization to this end.

The dependence of concepts on words was stated in its most uncompromising form by Max Müller(34).

What we have been in the habit of calling thought is but the reverse of a coin of which the obverse is articulate sound, while the current coin is one and indivisible, neither thought nor sound but word.

We know from studies in aphasia, such as Head carried out, and from many experimental inquiries how untenable this extreme view is. But there is much convincing evidence that words aid thinking and are for some conceptual processes indispensable—what C. E. Osgood has called the "representation level" of organization in cognitive processes.

Vigotsky, Luria and other Soviet psychologists(46, 25, 26) have emphasised the directive and adjuvant function of speech in normal mental development. Lublinskaya(24), for example, showed that children could differentiate signals much more quickly when verbal labels were attached to them, and that differentiations thus verbally reinforced were more stable and generalised than those elaborated without it. Similarly the Iowa workers—Spiker and his colleagues (44)—have demonstrated that when a child is given a common name for a set of stimuli, or a relation name (*e.g.*, middle-sized), he learns more quickly to generalize and discriminate in an instrumental task : assigning a verbal symbol, or label, to approved stimuli may make it more likely that a child will be able to transpose his learning to a new situation.

To determine how far this adjuvant role of words is held good for imbecile children, two of my colleagues in our Research Unit(16, 17, 18, 35, 36), Dr. O'Connor and Dr. Hermelin, devised and carried out during the last few years a series of experiments, some of which I should like to de-

scribe very briefly, though I fear that in doing so I shall rob them of their lucidity. O'Connor and Hermelin examined Luria's hypothesis that the significant deficit shown by poor verbal capacity is not so much an aspect of defective intelligence as an inherent difficulty in making the connection between words and motor behaviour. They found that though imbeciles (mean I.Q. 40) did not differ from normal children of the same mental age in certain tasks requiring discrimination and transposition, they were more quickly able to reverse a response previously learnt (*i.e.*, to move, for a reward, the larger of two black squares): whereas almost all the normal children could express the principle of discrimination in words referring to size, only one of the imbeciles did so. But when the reversal experiment was repeated with a group of imbeciles who were trained to state correctly in words that they had moved the bigger square each time that they did this, and then given the trials in which they were required to move the smaller square to obtain their reward, there was no longer a significant difference between the number of times they needed before they were successful and the number needed by normal children of the same mental age. It could be concluded that verbal reinforcement had made good a deficit in the imbeciles—a deficit which in other contexts we might regard as an advantage. They forsook a learned motor habit too easily, until a word—a concept—reinforced it, or, as we might put it, until verbal self-instruction induced a "set" which caused negative interference when the opposite choice between stimuli was imposed on the task. Their behaviour was the antithesis of that which might be shown by an obsessional or by a patient with organic cerebral disease who perseverates. It is open to several theoretical interpretations. It might be, as Luria supposes, that defectives are handicapped by a failure (in Pavlovian terms) to bring the second signalling system, which operates with words, fully into intimate and regulatory relation with the system that determines motor behaviour.

But whether the interpretation be along the lines of Pavlov's or Skinner's or Osgood's theoretical formulations, it is evident

that the use of verbal symbols, and especially those which refer to connections that have meaning, is the *pons asinorum* of defectives. If they can be helped to cross that bridge they have advanced considerably and may even be on the road to a modest literacy, such as Itard struggled so hard to attain in poor Victor.

In the next experiments imbeciles learnt to transfer a verbal response (a three-letter noun) from a pictured object to its written equivalent, and then to discriminate between each of the written words and two others with one letter different. Finally when they made ten correct choices of written words in succession, the subjects were presented with the four written words and asked to say what these were, so that their "reading score" (the number of correct responses out of a possible twelve) could be assessed. Before the experiment these imbecile children had failed to pass Burt's scholastic reading test at the four-year old level; now they learnt to read and they retained to some extent what they had learnt. They improved further in their ability to discriminate between written words after they had traced the letters of the correct word with their fingers, thereby suggesting that the relation between motor and verbal modes of behaviour may still be one of weak reciprocal aid. The simple conditioning technique used in this experiment is, of course, a familiar if old-fashioned way of teaching a child to read: here its interest lies in the demonstration of what reinforcement and practice can achieve in this domain for severely retarded children. The experiment also demonstrated that the conditioned response could be very rapidly transferred to new material, when the task was changed—a potentially important finding.

In further investigations into discrimination of written words, O'Connor and Hermelin selected 24 children of I.Q. 30-39, mean I.Q. 33.7, and having trained them to discriminate a printed word from three others (each of four or five letters) varied the size of the letters (height between 3 mm. and 10 mm.) in a determined sequence, to discover whether changes in size helped the defectives to learn to discriminate shape, or hindered them in this,

through being mistaken for the relevant attribute of the stimulus display. The result was in keeping with G. A. Miller's (33) findings. Shape discrimination was found to be easier when alternative discriminatory features in another category of visual stimulus, size, were also offered, provided that the subjects had not in their first discriminatory tasks been able to rely on constant size in the letters of the cue word whenever exposed. A learning set could be established in the first stages of the experiment which worked for or against the generalisation that size of letters mattered in discriminating between words.

The same investigators found that when imbeciles (I.Q. 40) had learnt to repeat a number of unrelated words, it was significantly more difficult for them to learn an equal number of familiar words which were synonyms of the first; but if a second lot of words was given, related by sound instead of by sense to those first learned (e.g., rhyming with them, as in "heel" and "meal"), then learning the second lot was facilitated: if the two sets of words were not connected by sound or meaning, there was neither advantage nor disadvantage from having learnt the first set. In part this conformed with the learning behaviour of normal young children; similarities in sound help association between words. But it also indicated—contrary to Luria's findings—that in these defectives some semantic generalisation takes place, and causes interference. Moreover when O'Connor and Hermelin asked their imbecile subjects three months later to give their first associations to the words contained in the original test set, and classified the responses, it was clear that those who had in the previous experiment been given synonyms to learn now gave a majority of meaningful associations (85%), whereas those who had previously had sound-connected sets to learn, or sets unconnected either by sound or meaning, showed no significant preference in their associations and did not differ materially in this respect from a control group who had not taken part in the experiment three months earlier. The tentative conclusion is that in these imbeciles training in learning semantically connected words leads to an

effective "set" which is relatively stable, and educationally valuable.

You may interrupt at this point to ask what all this has to do with the medical aspects of mental defect. Very interesting to academic psychologists, no doubt, but clinically trivial, and unpractical. To this objection I would reply that studies which throw light on the defective's ways of thinking and learning can hardly be trivial, nor, if they further his use of language, are they unpractical. Consider the three great Frenchmen whom I have already quoted: Itard (19) thought it worth his while to struggle for four years to teach Victor to speak and read: Séguin (43) asked us to picture "the difficulty, the weariness, the exhausting, heart-breaking efforts that these experiments entail for the teacher": he is referring to the experiments in which he tried to teach the hydrocephalic defective Amedée how to articulate words distinctly, and to read them; and Alfred Binet at the end of his joint *Mémoire* with Simon on the intelligence of imbeciles, pleaded eloquently for experimental study of the process of thinking and especially of generalisation. If a more modern justification is called for, it is surely implicit in our therapeutic aims. We want defectives to lead as happy and socially normal a life as possible. A socially normal life in literate societies presupposes, even at a low level, some education. It calls for acts of decision, and even, in very simple terms, for discrimination between words: to take a crude example, the defective going about in a modern city needs to recognise the symbols which distinguish public toilets for men from those for women, or the numerical symbols which denote the particular bus he wants to use. If he is capable of engaging in some productive occupation, his ability to connect symbols with concepts, and concepts with motor behaviour, is of social importance—though occupational adequacy is far from being the whole of social adequacy. As Sarason and Gladwin (28) have lately emphasised, our culture makes demands on learning capacity in all those, severely subnormal or not, who are trying to live in society. This is no novel view; the most cogent declaration of our duty towards defectives in this regard

was made by Binet and Simon in 1907(2). Reviewing the pedagogic and other reasons for retaining in special schools what they call verbal work, alongside the concrete manual tasks, they said :

These reasons apply particularly to the school. There are other reasons, social reasons, which are still more imperious. Nowadays, especially in towns, it is necessary that people should be able to read, write, count and express themselves appropriately. It has been rightly pointed out that reading is the triumph of abstraction and that a defective may take two years to learn to spell words out even at the most modest level : never mind, if the thing is possible, with however great an effort, that defective ought to learn to read. What matters is not the level of his intelligence, but his social status, and there he will suffer if he is illiterate. In questions of this sort, psychological and educational indications should give way to the demands of ordinary life ; necessity decides it.

The indications of psychology and education now point in the same direction as the demands of daily life.

It would be appropriate here to turn aside from imbeciles, so limited in their capacity to learn and think, in order to consider the social adequacy of that much larger group, the high-grade defectives. But before looking at this tangled issue I should like to refer, cursorily, to other studies of imbeciles carried out by members of our Unit—studies that are complementary to those I have been describing. They examined particularly the effects of motive upon performance, in its social bearings.

In a series of laboratory and workshop investigations(8,12,13,23) they demonstrated that the performance of imbeciles who had been given an external incentive improved significantly, when compared with that of a control group of imbeciles, in a variety of motor tests ; moreover the imbeciles acquired a skill—folding cardboard boxes—which improved strikingly when the social conditions in the workshop approximated to normal, in that each imbecile worked alongside a high-grade defective who did the preparatory glueing and the two boys constituted a working unit ; they could readily see their joint work and in most cases took pride in their attainment ; this was true even of patients with an I.Q. of

only 20 or so. Further experiments by Clarke and Hermelin(9) (which preceded Hermelin's studies of concept formation) showed that incentives act differently, as might be expected, upon imbeciles of diverse personalities : but an appropriate incentive brought the patients to the point at which they could perform repetitive tasks, of the sort industry requires, as well as high-grade defectives could. The imbeciles could thereafter partly support themselves through the payment they received, for work that gave them pleasure and satisfaction.

Since personality and personal relationships have been experimentally shown to have an effect upon the level which imbeciles can attain, we thought it desirable to examine the differences between severely subnormal children who remain in their families and those who have been committed to institutional care. In the ensuing survey by Grad and Tizard(14), there were 150 families with an idiot or imbecile living at home and 100 families with a similar defective child who had been in an institution for between one and 5 years. The children and their families differed in many respects, inevitably : and it is impossible to review briefly here the social and psychological characteristics of these two groups. The occupational data, however, bore out the experimental findings that there are considerable differences in the abilities of imbeciles which can not be attributed to differences in level of intelligence. A low intelligence score did not represent as severe a handicap as did a concomitant physical defect. Physical disabilities were, of course, common : half the patients, both those in the institution and those at home, had such disabilities, especially cerebral palsy and epilepsy. Gross multiple handicaps of this sort were, however, more frequent among the institutional patients. Although there were some almost untrainable and unemployable patients, burdened with an accumulation of defects, it seemed that with suitable training at least 10 to 20% of imbeciles can be employed in useful remunerative work, provided there are economic conditions of full employment, and satisfactory care for them at home or in a hostel.

Defects of temperament were among the

handicaps many of these imbeciles exhibited: some were restless and excitable, others torpid and apathetic. Among the 150 imbeciles over the age of 16 in this investigation, 13% were judged to be over-active or almost uncontrollable, and 28% sluggish and inactive, but of course these summary epithets do not convey the varied anomalies of personality. The investigation cast light, sometimes heartening and sometimes disconcerting, upon the interaction between doctors and welfare or other workers, on one hand, and the severely sub-normal patients and their parents on the other. The social issues raised here were complex and crucial.

It is at this point that a British psychiatrist tends to leave the comparatively pure air of the field study and the experimental workshop for a sultrier atmosphere in which there is much contention about notions of sociopathy, and about enactments that seem to darken counsel. For in our recent Mental Health Act (29)—admirable in so many respects—there are, as I have mentioned already, some definitions which trail clouds of dubious nosology behind them. Please forgive me for saying more about them than I would if they bespoke only a national idiosyncrasy. I believe they reflect ideas about the nature of defect which are widespread and which are crowned with the nimbus of such adjectives as “progressive,” and “dynamic.” I am not sure they deserve these epithets.

The new Act banished the term “mental deficiency”: henceforth officialdom does not know this category, it has been swept away to the limbo where “idiocy” and “insanity” and “asylum” lie, waiting no doubt for the euphemisms that for the present have supplanted them. According to the Act the generic term “mental disorder” is extended to include “arrested or incomplete development of mind.” Three classes of mental disorder are defined—subnormality, severe subnormality and psychopathic disorder. So far so good: the decay that afflicts any word referring to an unpleasant reality has overtaken “mental deficiency”; and Parliament and the World Health Organisation urge us to say “subnormality” instead—no great hardship. But there is another term

defined in the Act—“psychopathic disorder.” The definition runs:

a persistent disorder or disability of mind (whether or not including subnormality of intelligence) which results in abnormally aggressive or seriously irresponsible conduct on the part of the patient, and requires or is susceptible to medical treatment.

This harks back to the recommendation of the Royal Commission, two years earlier, proposing that high-grade defectives and psychopaths

should be recognised as together constituting one main group of mentally disordered patients, the other two groups being the mentally ill and severely sub-normal.

It is, of course, in keeping with the strong trend, both in Britain and in the United States, to shift the emphasis in high-grade defect (or retardation) from intelligence alone to other features of personality, to minimise inherited as against environmental causes, and to use as a main criterion of such defect social maladjustment and emotional insufficiency. This standpoint has much in common with the current view, expressed by Masland, Sarason and Gladwin (28) that

cultural and environmental factors . . . through the establishment of unhealthy or inadequate patterns of intellectual response, may prevent the optimum functioning of the mind in a person whose nervous system is basically capable of normal activity [and that] “within certain broad limits one can distinguish those mentally subnormal individuals whose disability is attributable primarily to a demonstrable defect of brain structure or chemistry from those whose malformation is the result of hearing deficiencies resulting from unfavourable environmental influences.

The advantages of this way of looking at the matter are manifest, but it is sometimes pushed so far that intelligence, about which we know a great deal, is played down in favour of emotional development and social fitness, about which, on the whole, we still know little. The approach can be a stimulating one for research, but over-zealously adopted it could have a retrograde effect

upon administrative and clinical practice, in which the new legislation adjures us to follow it.

The distinction I am drawing is perhaps too sharp: scholastic and intelligence test performance is still the main criterion of diagnosis for subcultural defect or feeble-mindedness, but the auguries point to its supersession. The *Manual on Terminology* (1) recently published by the American Association for Mental Deficiency lays it down that mental retardation is

subaverage general intellectual functioning which originates during the developmental period and is associated with impairment in one or more of the following: (1) maturation, (2) learning, and (3) social adjustment [and states that] "social adjustment is particularly important as a qualifying condition for mental retardation at the adult level, where it is assessed in terms of the degree to which the individual is able to maintain himself independently in the community and in gainful employment as well as by his ability to meet and conform to other personal and social responsibilities and standards set by the community.

To use such concepts as these for purposes of research will be an arduous and slippery business. What its consequences might be when applied in epidemiological inquiries can be inferred from the instructive findings reported in the thorough and valuable Onondaga County Study. Dr. Gruenberg and his colleagues (11) found that standards vary strangely, such factors as colour of skin and place of residence affected the ascertainment of children judged to be mentally retarded; mental retardation, Dr. Gruenberg concluded, is "a complex set of manifestations of some children's relationship with their immediate environment." This is true, but such complexity cries out for heuristic simplification: otherwise confusion threatens. The conscientious inquiries into the effect of cultural background on the diagnosis of retardation which are reviewed in Sarason and Gladwin's comprehensive report seem to indicate that in this area

"Chaos Umpire sits

And by decision more embroils the fray
By which he reigns."

While we struggle in this darksome realm, it is hazardous to put our trust in shifting semblances: or, to be more explicit, in social and emotional indices that vary with the observer and, more disconcerting still, vary with the environment. In her trenchant critique of psychiatric findings, which pillories many a lapse from logical and scientific rectitude, Barbara Wootton (48), herself a sociologist, takes up this weakness, states it in a clear proposition and explores its corollaries. Recognising that mental defect tends increasingly, in Great Britain at any rate, to be diagnosed, not by an intellectual test but by the defective's inability to accommodate himself to the demands of a highly industrial society, she takes the next step—which is to recognise that

if, as may be supposed, the capacity for social adjustment conforms to a more or less normal pattern of distribution, the cut-off point at which this defectiveness is held to be established must depend upon how exacting this demand for adjustment happens to be

so that it can come about that the criterion of defect may depend upon such completely adventitious factors as the state of the employment market.

In a less sophisticated age we should have said that one of the merits of full employment was that it made it easier for mental defectives to obtain employment. Now apparently we have to say that it actually reduces the number of such defectives. To appreciate the full significance of this situation we may imagine what would happen if similar reasoning were applied to the analogous case of some incontestable physical disability, such as the loss of a limb. Full employment certainly makes it easier for legless persons to get jobs, but no one in his senses would take this to mean that under full employment there are fewer persons without legs. Similarly full employment makes it easier for ex-prisoners to get jobs; but that is not to say that full employment diminishes the number of ex-prisoners, as distinct from the number who are able to get employment. Such statements would be manifestly absurd; but their absurdity well illustrates the difference between a disability which is established by a criterion that is, and one established by a criterion that is not independent of current standards of social competence.

And, Lady Wootton adds,

so long as defectives are subject, as they are, to legal and other disabilities, the significance of this difference is much more than semantic. If defectives are deprived of full civic rights and responsibilities, and even in some cases of their personal freedom, and if the number of defectives varies with the state of the employment market, it follows that some people are liable to lose their status as fully responsible citizens or to be deprived of their liberty, merely because employment is bad.

Lady Wootton's argument, thus lucidly stated, seems cogent. I say seems, for we psychiatrists, sublimed students of complexity that we are, distrust lucid arguments: convincing syllogisms, we suspect, are superficial, and what seems obvious is probably incomplete and over-simple. But surely in this instance we must concede something to the criticism: and we must admit that if we fall in with the tendency now to equate "high-grade defect" with "psychopathic personality" because of the relativity of the two concepts and their essential dependence on some standard of social competence or adjustment, it will widen unduly the social door of entry into a traditionally medical category. In Tredgold's well known textbook of *Mental Deficiency* (45), we may read that

it is probable that if the real nature of mental defect were more generally appreciated many, although not all of those who are called psychopathic personalities would be found to be certifiable under the Mental Deficiency Acts.

Such an affirmation raises issues which far transcend the apparently diagnostic and semantic questions. It is pleasanter to consider Jastak and Whiteman's (20) conclusion that

the retarded do not impose a disproportionate load upon community resources either in the form of legal infractions or excessive demands for social services . . . mental subnormality, it appears, need not connote an inability to fill an acceptable social role.

I would like here to underline the distinction between social criteria, and social determinants, of defect. Nothing I have been

saying is intended to minimise the manifest importance of the social factor nor the potency of emotional pressures and twists. Quite the opposite. A large part of the studies in defect by our Research Unit has been directed toward the social problem, as the title of O'Connor and Tizard's book (37) made clear. And as for the role of emotion, I would recall a passage from *Leviathan*

Naturall wit consisteth principally in two things: celerity of imagining . . . and steady direction to some approved end. On the contrary a slow imagination maketh that defect, or fault of the mind, which is commonly called dullness, stupidity . . . And this difference of quickness is caused by the difference of men's Passions . . . And the difference of Passions proceedeth partly from the different Constitution of the body, and partly from different Education.

It was the same Thomas Hobbes who said "The Light of humane minds is Perspicuous Words." In the psychiatry of defect our words will become perspicuous and the concepts they denote illuminating only if we probe further into how constitution, education, environment and emotion determine those differences of intelligence which Hobbes thought fundamental between man and man.

And so I finally come to causes. In psychiatry we seldom distinguish sharply between etiology and pathology; and in the network of preceding events it is profitless to insist on a strict hierarchy of causes, epidemiological, psychological, clinical and the rest. It is, however, plain that in the whole area of defect prospectors equipped with new tools can hope to "strike it rich." The vein has already been opened by metabolic studies, and by the genetic investigations that have revealed peculiarities in chromosome formation in mongolism—both, as Linus Pauling (40) lately reminded us, matters of molecular structure about which knowledge is decidedly on the move.

What is known and what is inferred about the etiology of defect has been critically reviewed within the last year or so by Professor MacMahon as well as by Dr. Masland (27, 28). Their masterly surveys make detailed consideration by anyone else

superfluous for the present. However, among the diverse studies I should like to single out for reference those of Professor Pasamanick and Dr. Knobloch and their associates (21, 22, 38), because of the care with which their data have been collected and analysed and because of the attractive explanatory hypotheses they offer. I need not recapitulate to this audience the arduous investigations through which they believe they have demonstrated that disturbance in the circumstances of pregnancy and birth can bring about a continuum of cerebrogenic anomalies, manifest as disorders of behaviour, reading difficulties, tics, defect of varying degrees, cerebral palsy, and epilepsy. The complications of pregnancy (such as toxæmia and bleeding), dietary inadequacy in the mother during the months of pregnancy, abnormal delivery, and premature birth were judged responsible for sub-lethal (as well as lethal) misfortune to the child. Mental retardation, according to their findings, is conspicuous among the sub-lethal consequences that may ensue when the reproductive process is deflected from its normal course. If retardation is accompanied by physical evidence of neurological damage, a relation of cause and effect is habitually and widely accepted, at any rate so far as perinatal damage is concerned: but the challenging conclusion of Knobloch and Pasamanick urges us to consider that lesser degrees of prenatal and perinatal cerebral damage may produce defects unaccompanied by detectable neurological signs, defects which are commonly attributed to heredity and post-natal influences. The body of evidence they have produced as warranty for these conclusions is impressive; and some of their more specific hypotheses are provocative, especially that which connects insufficient diet—perhaps of protein—during the critical early months of pregnancy with mental retardation in the child. Still more provocative are some recent developments of Pasamanick's views. Incorporating his continuum of reproductive casualty with Locke's and Helvetius's *tabula rasa*, he supposes that men are conceived equal in intellect (apart from a few who inherit neurological defects), and that it is exogenous brain damage, "life

experience and the socio-cultural milieu influencing biological and psychological function," that make us differ one from another. This rather egalitarian hypothesis would exalt the power of environmental influences high above their wonted credit: if it proves correct—and no one can call it incorrect who has not examined with equal care Pasamanick's evidence and the contrary evidence which speaks for polygenic inheritance as the main determinant of human differences in mental ability—then the possibilities that open out do not merely concern the prevention of defect and other ills, but the raising of normal human capacity throughout the population. This would afford yet another instance of the wheel turning full circle. When Séguin devoted himself to experiments in educating idiots and imbeciles, he arrived at principles which had a larger scope than his medical obligations towards the defective. At the end of his book he wrote:

But if by a turn of the wheel, in compensation as it were, it happened that the solution of a very small problem brought with it the solution of a very general one; if it happened that while working away to settle the modest question of how defectives should be educated, one had found a formula precise enough to be applicable to education generally . . . then not only would one have rendered some service in a relatively humble sphere, but one would have laid the basis for a scientific method of education.

It is unlikely that Pasamanick shares all the St. Simonian optimism of Séguin: but in such experiments in preventing defect as he now advocates, lies much hope of illumination.

Few of us psychiatrists can have a clear conscience about mental defect. We have given it less attention than it required, and research has only belatedly concentrated on the pitiful and involved problems which it thrusts upon the clinician's notice. Now that much serious inquiry is in progress, it seemed fitting that the Adolf Meyer Lecture should be devoted to a cursory glance into this large area of research and action. I have not tried to do in one lecture what 21 notable contributors aimed at accomplishing in the Woods School Conference

(47) last year. Their survey and the current list of projects supported by your Department of Health, Education and Welfare show that the vineyard calls for diverse labourers to cultivate it in many places. I have referred to some work of which I have immediate knowledge, and to studies which illustrate the close interplay between developments occurring outside medicine and certain kinds of research that have been fruitfully prosecuted to elucidate and control defect. The work now in hand is inspiring. It looks as if future lecturers who choose this theme may have a rich harvest to report.

DISCUSSION

PAUL V. LEMKAU, M.D. (Baltimore, Md.).

—We are indeed fortunate in the privilege of hearing one of Dr. Meyer's most brilliant students deliver this Adolf Meyer Lecture. Sir Aubrey Lewis' choice of subject is particularly appropriate since it brings before us a relatively neglected field. Dr. Meyer also tended, in his more or less obsessive all-inclusiveness that some of us remember so well, to pick out that area for discussion that seemed for the moment to be eclipsed in the blaze of light from some other interest in psychiatry.

There are a few points in Sir Aubrey's discussion on which I would like to enlarge. The statement is made that the field of mental deficiency is a rapidly moving one, replete with new research findings. Because of them, the specialists in pediatrics are, in this country at least, remarkably stirred. It is mostly pediatricians who are doing the teaching about the discoveries regarding the genetic defect in mongolism, and it is they who are spearheading new research institutes to look further into the

genetically determined metabolic disorders. Public health authorities have responded vigorously to the new knowledge, perhaps too vigorously. I heard a while ago that the New York City Health Department had run some tens of thousands diaper tests in hospitals and had yet to discover its first case of disorder of phenylalanine metabolism. But the test is very cheap and the cases which will certainly eventually come to light will have a chance to avoid phenylketonuri deterioration. That the manufacturers of test substances for ketonuria were all exhibiting at the American Public Health Association annual meeting but are not in evidence here at the annual meeting of the APA so far as I have noticed is evidence in favor of Sir Aubrey's conclusion that psychiatry neglects mental deficiency as an area of action.

Sir Aubrey noted that the Royal Commission urged a distinction between the mentally ill and the mentally defective as a practical measure. Paper number 123 of this meeting will report a survey of cases seen in out-patient services in Maryland. The abstract doesn't indicate that Mrs. Bahn intends to take up a point the survey made clear, so I will introduce it here. Analysis of the data by total number of visits to clinic by diagnosis showed that some diagnostic groups had very few visits while others showed treatment of somewhat greater length. Those conditions with the fewest visits carried the diagnosis of mental deficiency and mental diseases associated with aging. Those with the largest number of visits included psychoneurosis, the so-called functional psychotic states, epilepsy and character disorders. Except for character disorder or, as Sir Aubrey refers to them, psychopaths, which is often a diagnosis made at the end of long but unsuccessful treatment, the distribution of length of treatment seems to correlate rather well with prevalent notions about treatability; to put it bluntly, the clinics worked hardest and longest where they suspected success would be possible.

There is, of course, real reason to question whether this sort of categorization really holds. There are a number of reports in the literature indicating that some senile states respond well to treatment when treat-

ment is carefully adopted to the discovered needs of the patient. In the field of particular concern of Sir Aubrey, the long term prognosis is quite good, since all studies indicate that diagnosed mental defect is much more common in children than adults, and that the differences are not due to differential death rates. Lest you should feel this is merely an epidemiologic trick, let me point out that for many purposes the criterion of social adjustment sufficient to avoid medical or sociological detection of disease is a quite reasonable definition of health. On the basis of prognosis it is difficult to defend psychiatry's tendency to give short shift to mentally deficient patients. We have done it so long, however, that parents of such children don't like us very well anymore and turn to people who take a more realistic, in this case optimistic, so far as social adjustment is concerned, viewpoint in the matter.

The essence of the wish to separate mental deficiency from mental illness seems to me to rest in the recognition that mental deficients have, usually, a more or less static handicap so far as intelligence is concerned, though, as already noted, not in social adjustment. There is evidence, of course, that in some cases intelligence levels can be raised, but cases in which this can be achieved are still relatively rare. That test-intelligence is relatively static, however, does not mean that other personality parameters will share the stultification. There has been, perhaps, too easy a generalization that intelligence is an indicator of what the whole person can and will do. The evidence appears rather strong that maturation in other personality assets is not necessarily bound to the intellectual limit.

Sir Aubrey referred to the work of Pasamanick, Knobloch and their collaborators in the area of reproductive wastage and its consequences for survivors. This work rein-

forces the idea that the problem of the prevention of mental defect rests in insuring that the inherent capacities of the organism are protected and maintained. They have showed some of the places we must look for agents that can, too often irretrievably, reduce the *capacities* of the individual that are at their maximum at the moment of fertilization. From that moment on, the *inherent* capacity of the individual can, so far as we now know, go in only one direction, downward. The preventive task is to free the individual so far as possible from loss of capacity. Pasamanick and Knobloch have illustrated areas in obstetrical and pediatric practice where opportunities for prevention exist, but they have also showed, in their work on later development, that postnatal environment, in terms of psychological and sociological determinants offer equal and, probably, more available opportunities to protect inherent capacity.

One further point and I will stop pursuing the multitude of ideas stimulated by Sir Aubrey's presentation. The relative stability of defect states implies the newer types of psychiatric services that are now developing. We hear much of the deleterious effect of hospitals on people kept too long. This thinking is not applied so frequently to the effect of institutionalization on the mentally defective, though there is no reason to suspect that it is different. If it makes sense to offer home services to the schizophrenic or senile patient released from hospitals as soon as his severe behavior disorder is controlled, it must make sense to offer services easily available to the caretakers of mentally defective persons in the community. The development of such services and of the patterns of administration suitable to make them maximally effective are among the challenges presented to us in Sir Aubrey Lewis' very informative essay.

BATTEMENTS AND BRIDGES IN THE EAST : THE CZECHOSLOVAK PSYCHIATRIC CONGRESS WITH INTERNATIONAL PARTICIPATION¹

JULES H. MASSERMAN, M.D.²

It had long been my avocation while travelling about the world to learn how my colleagues elsewhere observe facts and form opinions—and to acquire a growing insight that the distinctions among “facts” and opinions are not as absolute as I had formerly imagined. When, therefore, I received an invitation from the Czechoslovak Ministry of Health to be “an honored guest and principal speaker at the First Czechoslovak Psychiatric Congress with International Participation,” I welcomed an opportunity to help re-establish long-suspended relationships with our colleagues within the Soviet zone of influence, and attended the Congress at Jesenek, from September 7 to 11, 1959. The following is a highly condensed report of its proceedings.

BACKGROUND OF THE CONGRESS

During the later periods of the Stalin regime, and especially during his prewar purges, all non-Marxist psychologic or sociologic ideologies grew increasingly suspect in the USSR, and those that could be considered anti-Marxist became anathema. To replace psychoanalytic and other “idealistic” theories, Pavlovian reflexology was elevated into a “materialistic organon of higher nervous function” which was to explain all behavior. This approach also seemed to offer two convenient corollaries : (a) that men differed according to their “neurophysiologic type,” thus justifying various assignments to different levels of responsibility, duty and reward and (b) that men could nevertheless be “conditioned” by appropriate “first and second-order stimuli” (*i.e.*, an appropriately controlled physical and symbolic environment) to achieve almost any kind of social adaptation, thereby also fulfilling a requirement (succinctly restated by Myasischev at the Congress)

that “*Marxist philosophy could not admit that man was basically irrational.*” However, during the interregnum of the Triumvirate, of Malenkov, and in the early days of Khrushchev, the freedom of investigation demanded by the nuclear physicists and temporarily given to writers, poets and composers was also extended to psychiatrists, who for a time responded enthusiastically and productively. Unfortunately, there recurred an intensification of the cold war with another tightening of the reins and a second wave of retractions and retrenchments—but again most recently, with a second thaw in international relations seemingly in the making, another era of communication and rapprochement in the sciences and the humanities seemed at hand. It was to take advantage of this that the Congress was planned in a land that had always been an ethnic meeting-point for East and West, and by scholarly and foresighted men who were personally acquainted with the best traditions and scientific resources of both.

PROCEEDINGS

After the usual addresses of welcome by Chairman O. Janota and various civil dignitaries, F. Knobloch of Prague University sounded what he hoped would be a conciliatory scientific theme for the Congress by pointing out that both “micro” (*e.g.*, physiologic and animal experimental) and “macro” (*e.g.*, individual or group analytic) studies were indispensable; *i.e.*, altered metabolism or physical trauma can affect cerebral tone and excitability, and “thus derange the temporary neural connections which develop in the process of habit formation.” After other such efforts to collate physiologic terminology and Pavlovian structuralism with the concept of effective residues of individual experience, Knobloch appealed for greater “collaboration of investigators from varied lands and standpoints.” But this moderating position was challenged by O. Vymetal, of the University

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² The Medical School, Northwestern University, Chicago, Ill.

of Olomouc, in a polemic idiom with which one soon grew familiar. Said Dr. Vymetal, "It would be too undialectic to absolutize one theory, but also eclectic to be complex . . . All Western philosophical orientations, in particular neopositivism, existentialism, and pragmatism combine an erroneous ontological outlook necessary for scientific idealism and their principles are not utilizable for scientific theory. We start out from the principles of Marxist philosophy, dialectic and historical materialism. This serves as a protective screen against further errors." Vymetal's position was apparently endorsed by the initial spokesman for the Soviet delegation, N. Myasishchev of Leningrad, who likewise asserted that "materialistic psychology is uncompromisingly antagonistic to psychoanalysis, existentialism, biodynamic theory (*sic*) and other theories. Only socialism can develop proper moral-psychologic characteristics and so prevent neuroses due to non-adaptational cortical reflexes. Psychotherapy, must therefore consist only of adjustments to reality and collective work activity." P. W. Bassin of Moscow stated even more explicitly that "since the beginning of this century, Soviet psychiatrists had anticipated Hartmann, Kris, and Loewenstein in their devastating criticisms of Freud," that Soviet science absolutely rejected all forms of Freudianism as a "reactionary, mythological idealism," that Freudian psychoanalysis had therefore been stamped out in the Soviet Union and, Bassin obviously implied, should be treated similarly if it reappeared in any of the associated People's Republics.

It was at this somewhat difficult juncture that I was put in the position of official spokesman for Western psychiatric thought. Sensing that the presentation of technical research which had been originally requested by the Congress Secretariat would hardly be appropriate to the situation, I first conveyed the official greetings from various Western scientific societies as authorized,³ and then spoke extemporaneously to the following effect :

We of the West employed three major approaches to the understanding of human be-

havior : the historic-philosophic, the comparative-experimental and the interdisciplinary-integrative. In this we were in obvious accord with our Soviet colleagues, since they, too, see man as the product of ethnic and politico-economic evolution, investigate even his highest neural functions in the objective experimental tradition of Sechenov and Pavlov, and study him currently by means of every one of the interrelated social sciences. Many of us in the West know this because we follow the Russian scientific literature—in fact, the U. S. Government subsidizes its translation—and because some of our leading neurophysiologists (*e.g.*, Karl Pribram, Horace Magoun, Grey Walter) had exchanged or were planning to exchange visits with Russians of the calibre of A. I. Oparin, A. Luria and (the late) Professor Bykov. Neurology is hardly a neglected science among leading psychiatrists in the West (*e.g.*, David Rioch, Ben Boshes, Roy Grinker), and even our orthodox psychoanalysts profess respect for Freud's basically biologic orientations. For that matter, most broadly trained psychoanalysts regard their sub-field as only (a) a special method of research into each patient's energy systems, personality development, unique concepts and values, and characteristic patterns of transaction, (b) a constantly improving but ever tentative set of correlated postulates about human behavior and (c) an individually adaptable, rather protean and essentially socially oriented mode of interpersonal therapy. Indeed, what we actually refer to by our somewhat unfortunate terms "psychology" and "psychoanalysis" is the integrated study of man's total adaptations to his material and cultural milieu, whereas our Russian colleagues really mean the same when they use the perhaps equally abstract concepts of "primary and secondary signals," "higher cortical analyzers and effector systems" or "conflicts between excitatory and inhibitory irradiations." As to ancillary experimental approaches, I could offer the Congress not only my own work, but studies by Gantt, Liddell, Pribram, Delgado, Mirsky and others that equalled in rigor and objectivity the classic experiments of Pavlov and, like his, led to certain basic biodynamic concepts of behavior that best fulfilled the criteria of breadth, economy and predictability required of truly scientific formulations. Certainly, the best psychiatric therapy everywhere utilized every available physical and environmental means to restore personal happiness and social usefulness. Excluding irrelevant economic or political considerations, then, it might well be that many of the differences between Eastern and West-

³ The American Medical Association, the Academy of Psychoanalysis, the Society of Biological Psychiatry and others.

ern Psychiatric thought consisted in the choice of words rather than in operational referents. In any case, we of the West, and perhaps all of those present, hoped that the Congress would help remove this semantic handicap to greater rapport and collaboration among us.

My talk ended the first day's session, and despite the courteously prolonged applause, there was no way of ascertaining whether it had been received as an admission of, and retreat from, Western confusions and weaknesses, as a challenge to conflict, or as what it was meant to be: a sincere offer to leave clanking arms and tattered standards behind in outmoded battlements, lower the drawbridges, and meet on common ground for friendly scientific concourse. That it was taken in all these ways—but fortunately mainly in the third sense by most of the leading Russian delegates—became apparent as the Congress progressed. The first indication of this beginning rapprochement occurred at a round-table discussion on Concepts of Neurosis scheduled that evening.

When again asked to contribute to the discussion, I reviewed the neuropathologic connotations of the terms "neurosis" and "psychosis" from Cullen and Feuchtersleben through the kaleidoscopic meanings of Kahlbaum, Charcot, Freud, Sullivan, Fromm, Jaspers, and then back again through Eysenck and Guiliarovsky to currently renewed assertions that "neurosis is simply a disease of the higher nervous system." I stated that we could agree even with this if the term *disease* were taken quite literally to mean a "dis-ease" or disruptive un-easiness experienced by an individual under circumstances that he had somehow come to regard as stressful and threatening. In such conditions (or, in Russian, with such "conditioning"), the subject would be called "neurotic" if he reacted with various physiologic (autoplastic or "psycho-somatic") and social-transactional (alloplastic) disturbances greater than those thought to be necessary or appropriate by most observers—yet not sufficiently severe in intensity and duration ("psychotic") to justify forced isolation and treatment. However, in view of the current expansion of the term "neurosis" to cover so many viewpoints, vectors and contingencies, perhaps we would sooner or later abandon it as no longer of etiologic, diagnostic or prognostic value, much as we no longer accepted the previously literal meanings of Hippocrates'

"frenzy," Galen's "hysteria," Kahlbaum's "vesania," or Prichard's "moral insanity." Instead, just as the physicists outgrew the notions of "phlogiston" or "cosmic ether" and progressively sharpened their lexicon, so should we also accommodate to more modern and scientific concepts of behavior and its vicissitudes.

Perhaps this discussion constituted a bit of a gambit, since I knew that in some sections of the Russian literature neuroses were considered to be quasi-neurological diseases subdivisible into neurasthenia, psychasthenia and hysteria, and my presentation of predominant Western views had definitely challenged this position. The reaction was not long in coming: as rendered by the English interpreter, a psychiatrist from one of the Eastern countries once again characterized me as "obscurantistic, unscientific, misleading, deviationistic, idealistic" and, as a final epithet, also "religious." I learned later that he had begun a third sentence—which the translator omitted—to the effect that my views served the interests of "American capitalism and imperialism"—but at this point the speaker was abruptly cut off by the Chairman as being completely out of accord with the scientific and fraternal spirit of the Congress. The Chairman's remarks were fully translated into all of the languages and were soundly applauded as an edict that this type of political and ad-hominem polemic would no longer be countenanced.

Relations were further improved by efforts of Eric Wittkower of Canada, who had arranged an "Informal Seminar on Psychosomatics" with Drs. Snieznievsky, Bassin and other leaders of the Russian delegation. Word of this had got around, and by the time the seminar assembled, it had acquired a multilingual and highly effective moderator in the person of Dr. Chertok of Paris and an audience of over 100 eager psychiatrists from nearly every country represented at the Congress, all of whom apparently anticipated not only fresh information but also that interplay of move and counter-move which makes chess so intriguing to Eastern intellectuals. Despite a special invitation, I had not intended to be present at this seminar for a number of reasons: first, that I had already used my fair share of time (I had been given a sec-

ond hour in a full Congress session to present my data and motion picture films); second, that I did not want the inference drawn that we were staging a Western vs. an Eastern team debate—or indeed, that there was any official “Western Delegation” at all; and third, I had full confidence that Wittkower could ably continue to represent modern holistic views in the field. However, some two hours after the seminar began, I passed through the Conference room expecting the meeting to be over, and instead was immediately drafted by the Chairman into what was an apparently amiable but highly animated discussion.

The question at issue, it seemed, was the key concept of *regression*. The Russians claimed that this simply meant an atavistic return to simpler forms of mesencephalic behavior in the presence of physiologic or pathologic cortical impairment, whereas Wittkower advocated the analytic-dynamic version that a person placed under any form of stress tends to resume just those patterns of conduct more specific to his own early years: e.g., an ulcer patient reenacts and suffers from the motile and gastric hyperactivities of the hungry child. Since neither Drs. Bassin nor Sniezhnevsky were willing to accept derivative clinical interpretations to support psychoanalytic premises, could I, the Chairman asked, furnish any experimental evidence bearing on the problem? I recollected several such bits of evidence: e.g., D. Levy’s record of a full-grown, agile dog which, as it became jealous of a rival pet, began limping again as it had done years previously when it was a puppy being tenderly nursed for a broken leg. Perhaps more fortuitously, I also adduced Pavlov’s own observations that when the terrors of the Leningrad flood abolished nearly all the conditioned reflexes in his dogs, *each reverted to patterns characteristic of its own early behavior*.

At this point Wittkower made an effective proposal: that instead of any further discussion of abstractions, each of us describe how he would actually treat, say, a 40-year-old male patient with a peptic ulcer. The Russians agreed, and outlined their procedure thus: first, they would take a complete personal history upon which to “base an understanding of the patient’s higher neural functions”; next, they would advise proper diets and prescribe drugs such as atropine, banthine, gastric alkalisers and mucoid gells to modify the “deviant conditioning of the neuro-somatic reflexes,” and finally, they would “foster counter-inhibi-

tion of the excessive higher neural excitation” by providing rest and relief from environmental stress—including, if necessary, “sending a telegram to the patient’s employer directing that his job be made easier.” Dr. Chertok (who as moderator, had sensed the possibilities of the interchange), Wittkower and I received this clinical outline enthusiastically; in fact, we pointed out that we might go even further; first, in securing richer details of the “personal history” through intensive analytic interviews, second, in neuro-somatic treatment by vagotomy or even gastrectomy if necessary, and third, by interviewing the employer personally. But I then raised a crucial issue once again involving regression and individual dynamics: suppose that the patient had been a deprived infant who had yearned for a devoted mother during childhood, and was now as an adult once more deeply disappointed that his wife did not properly fulfill a maternal role—would our Russian colleagues also “send a telegram” to the patient’s spouse directing her to treat him with greater kindness? Or better yet, would they, through personal influence and the communication of understanding, “decondition” the patient so that he (including his stomach) would no longer yearn for excess (ultraparadoxically conditioned) “cerebro-somatic” indulgence? Indeed, they would, said the Soviet psychiatrists present, whereupon the meeting adjourned for vodka in a spirit of jovial goodfellowship, the Russians claiming that we were really materialistic neurophysiologists at heart and Wittkower and I endowing them with the honorary title of psychoanalysts in training.

It was at this point that the members of the Soviet delegation cordially invited Mrs. Masserman and myself to come on a “professorial visit” to Moscow, and other representatives followed their lead with corresponding, but as yet necessarily unofficial, invitations to Poland, Rumania, and Hungary. Throughout the rest of the Congress there was a noticeable relaxation of tension, a greater mobility and freedom of communication and a generally increased atmosphere of professional friendliness—although, be it noted, all questions of economic systems, politics or international relations continued to be carefully avoided.

Later Sessions:—The next morning the conference was opened by Hans Hoff, Professor of Psychiatry at the famous University Polyclinic in Vienna and currently Presi-

dent of the World Federation for Mental Health—which, incidentally, the Soviet Zone countries, after an absence of ten years, were beginning to rejoin. Professor Hoff spoke eloquently of psychiatric problems that affected all nations: alcoholism, drug addictions, juvenile delinquency, and the many personality and cultural stresses that resulted from displaced populations, weakened family structures, changing social customs and industrial automation. No one could take exception to his review, nor his moving appeal to all nations for “human-co-existence”; on the contrary, he was accorded a deserved tribute.

Hoff was followed by E. Wolf (Prague) who, in a paper of comparable thoughtfulness, returned to the clinical problems of psychotherapy and correctly pointed out that the good results of various forms of psychiatric treatment did not necessarily prove the sometimes narrow and conflicting theoretical convictions of their advocates. In any case, the patient should not be permitted to regress to excessive dependence either on physical or symbolic-experiential therapies but should instead be treated with a degree of medical and environmental realism that would “inhibit the deviant behavior to the point of extinction.”

The rest of the Congress consisted of a diverse array of papers and discussions, representative samples of which, either read or distributed as typed abstracts, deserve mention under the following rubrics:

Child Psychiatry: T. Simson of Moscow attributed most childhood neuroses to “severe toxemias of pregnancy or childhood infections which affect the cortical cells . . . We understand neuroses from the position of Pavlov, either as overloading of nervous processes or as a deviation resulting from conflicting excitatory and inhibitory processes; nevertheless, such neural deviations may also be induced by errors in upbringing . . . in an unsmiling environment.” V. Kudriavtseva, also of Moscow, proposed that children with post-encephalitic aesthenia “due to cortical inhibition” should be given “more rest and easier tasks at school,” and J. Vitek of Prague gave it as his opinion that, “in nearly all of a series of cases of childhood neuroses, there were evidences of fine residuals of centrencephalic damage.” On the other hand, E. Bartsch of Berlin investigated the psychological effects produced in children

by frightening medical procedures and found that, if the hospital milieu were such as to make the child feel loved and protected, even encephalography left no physical damage or repressed dread. J. Fischer of Prague reminded us that we had not yet traced the vicissitudes of adult life to the traumatic experiences of infants or toddlers. In a group of 80 neurotics aged 7 to 17, G. M. Pivovarova of Moscow found “disturbances of carbohydrates and protein metabolism in all” and correlated these with a “weakened nervous condition and mental worry of long duration.”

General Etiology of the Neuroses: G. Destunis of Berlin could find evidences of hereditary factors in only 30 of his series of 300 neurotic patients; in the others, endocrine factors or physical traumata combined with psychological stresses to produce the disordered behavior. B. Alapin of Warsaw believed that fear of cancer and other neurotic symptoms in women could be attributed largely to a hormonal imbalance. C. Koupernik of Paris attributed many neurotic reactions to the traumata of loss, but pointed out that if, for example, a patient had been active in caring for a dying relative or friend, there might be a “free interval” of from one to three weeks after the loved one died before the neurotic reactions developed, and that a physician could intervene during this time to prevent or mitigate the onset of the neurosis. In this connection, J. H. Rey of London reflected that perhaps a period of mild reactive depression is favorable to eventual recovery, “since it is human to feel guilt which motivates the patient to make reparation to real or imaginary victims. Patients who cannot get depressed are difficult to treat.”

Special Etiology: A. S. Christovich of Leningrad, like Bruetsch of Indiana whom he did not quote, traced some psychoses to rheumatic encephalitis, and T. Nievzorova of Moscow attributed others to the misuse of ACTH. T. P. Hackett of Boston studied the deliria occurring after frontal lobe lesions and the hallucinogenic effects of thalamotomy, and concluded that both could be modified by psychotherapy. K. Szilagyi and his associates in Budapest could find no differences between normals and schizophrenics on the Quick (benzoate-hippuric acid) test. Z. Böszormenyi, also of Budapest, studied the effects of administering 0.75 to 0.80 mgm./K of diethyltryptamine intramuscularly to 24 psychiatric patients and 30 controls, and noted that the drug induced an “experimental psychosis” which lasted only 2 or 3 hours, but which was followed by “the appearance of latent artistic drives expressed in painting, poetry, etc.” H. Bultavova, *et al.* of

Prague also studied various anticholinergic hallucinogens, possibly related to those being investigated by L. Aboud in Chicago. However, J. Roubicek of Prague concluded that "Drug . . . experiments have not revealed the cause of endogenous psychoses, yet have founded a new field : experimental psychiatry . . . which can also utilize subjective experiences."

Psychiatric Therapy and Hypnosis : I. Hardi of Budapest treated various functional gait disorders by "electrotherapy, pharmacotherapy, narcoanalysis, and narcosuggestion." F. Volgyesi of Budapest, described his "Active Complexe Psychotherapie" as one that "turns to the cortex and is based on a purely intellectual approach" but did not correlate it with his previously advocated "Hypothalamic By-pass Hypnosis." I. Horvath of Prague reported that hypnosis induced "a marked facilitation of elective irradiation between cortical signalling systems, and good levels of extinction of old and working out of new conditioned reflexes which were quite stable after awakening, even when the patient could not verbalize the effect." S. Bethelm of Zagreb treated impotence by suggesting to mildly hypnotized subjects that they have erotic dreams, and noted that symptomatic improvement was heralded when the patients "dreamed of better contacts with the partner." V. A. Jasov of Moscow facilitated the induction and accentuated the effects of hypnosis by using barbiturates (especially the Soviet favorites, Medinal and Barmobil) but, like Bernheim three generations ago, wisely noted that the effects of this form of therapy are "conditioned less by the state of inhibition and more by the characteristics of the personality of the patient, the particulars of the pathogenic situation, the doctor-patient relationship, the content of the suggestion and the entire process of treatment." With this lead, N. Schipkowensky of Sofia warned again of the iatrogenic trauma of unskilled hypnosis, and recommended that deviant interpersonal behavior could best be resolved when both the patient and the therapist were fully awake. J. Dubois of Saujon also recommended a quiet environment and "affective neutrality" as most conducive to therapeutice results.

Alcoholism : The fifth and last day of the Congress was devoted to this topic, which is apparently as urgent a problem in the East as in the West. There were few claims as to single or even primary genetic, constitutional, developmental, dietary, psychologic or sociogenic causes for addiction to alcohol; faced with complex realities, serious workers in the field everywhere in the world soon abandon monothetic oversimplifications. Organic effects were

discussed by H. Casier of Ghent who noted that 10 to 12% of C-14 labelled alcohol was fixed in the tissue within 30 minutes, 25% in 3 hours, and that some still remained in the brain tissue after 15 days. Binding was most marked in the liver, which may account for hepatic cirrhosis in chronic alcoholism. P. Stokes, J. Reilly and O. Diethelm of New York thought they could correlate the emotions of alcoholics with specific chemical variations in their blood, whereas A. Povorinskii of Leningrad attributed the hangover to the "weakened hypnotic state of Pavlov." A. Bertrand of Paris found that alcoholism reduced industrial efficiency from 20% to 65% and F. Detengove of Tashkent observed that "ex-alcoholics become neurotic."

As to *treatment*, V. Borinievlch of Moscow regarded only the early stages of alcoholism as immediately amenable to psychotherapy, and J. Strelchuck of Moscow outlined the methods to be used for more advanced cases as follows : 1. Detoxication, vitamins and prolonged sleep, 2. The establishment of negative conditioned reflexes to alcohol, 3. Physiotherapy, psychotherapy and work therapy, 4. Enforced Antabuse medication for 6 to 12 months with 5. Reinforcement of the negative conditioning to alcohol as necessary. Zachepitskii treated alcoholism by "short conversations and collective hypnosis" ending with "negative conditioning for alcohol with the aid of apomorphine and thiurane." J. Duba of Prague reported that Stopethyl may safely be substituted for Antabuse, since patients cannot abolish its anti-alcoholic action by drinking vinegar. J. Dent of London observed that in alcoholics as in other neurotics "to be or not be—that is the anxiety." So why not drink, since we shall not die until tomorrow? But instead of "lulling the forebrain with sedatives," Dent recommended "stimulating the back brain with apomorphine." H. Faure (Bonneval, France) advocated three weeks of narcosis with barbiturates and Largactil, during which the patient was to be awakened thrice daily for "dream analysis, transference interpretations, group therapy and exposure to tape and motion film recordings of his previous behavior while intoxicated." J. Carrere (Epinary-sur-Orge) also insisted that his patients view motion pictures of their conduct during alcoholic-amnesic states, and reported that of 65 so treated since 1954, 29 have remained complete abstainers and 24 more "improved."

Other papers devoted to the *public health* and *legal* aspects of alcoholism may be summarized as follows : A. Tongue of Lausanne asserted that whereas the toxic effects of al-

cohol on social behavior varied from culture to culture, the alcoholic everywhere must be held responsible for his conduct. P. Jean of Paris indicated the extent of alcoholism in France by noting that his government now paid 80% of the cost of 3000 beds in public mental hospitals, and 1000 more in private ones, all devoted exclusively to the treatment of alcoholics. M. Marzynski of Lodz reported that the Polish Government "refused to use legal punishment, but insisted that the alcoholic undertake obligatory out-patient or group therapy." J. Skala, *et al.*, of Prague reviewed the Czech Government's program, instituted in 1956, of individualizing the treatment of neoabstinents vs. occasional or impulsive, vs. consistent or chronic alcoholics; however, he hoped that a revision of Law 87 "would stress educational and economic weapons rather than repressive ones."

And thus ended a meeting of nearly invariably informed, keen and eager minds assembled, for the first time in over a generation, in a Psychiatric Congress with truly International (East-West) Participation.⁴ To say that far-reaching scientific, philosophic, or even methodologic accords were reached would be unrealistic, but to deny that mutual understanding and respect were fostered that might lead to greater rapprochements in the future would also be to underestimate the undeniable success of the Congress.

⁴ Since the proper editing of a professional report is not conducive to the expression of personal sentiments, this last paragraph on Czechoslovakia should, I suppose, have been discarded by my cortico-differential analyzers as an idiosyncratic artifact. But art or not, the fact remains that my most significant memories of the Congress concern not its surface proceedings but the unfailing graciousness of our Czech hosts to every representative of every country, the growing warmth and cordiality the Russian and other Eastern delegations displayed toward nearly all the visitors from the West, and the half-embarrassed gift-giving and the undeserved but sincere expressions of gratitude from a spontaneously assembled farewell delegation on the occasion of our departure. But even more poignant were the final remarks of one newfound friend still separated from us by a curtain of governmental distrusts and suspicions: "Please write—but until official matters between our countries clear as we hope—don't yet write too often!" Nor is it much comfort to recollect that there are always two sides to a curtain, and that we, too, may still be impelled to make a like remark to a visiting Soviet scientist.

DISCUSSION

NATHAN S. KLINE, M.D. (Orangeburg, N. Y.).—This paper by Dr. Masserman constitutes a model for the reporting of conferences. He has accomplished the extraordinary feat of not only succinctly summarizing the contents of a vast number of papers but also portraying the dynamics of the conference itself. Since I had the opportunity of lecturing at Charles University in Prague only a few weeks before the conference I can attest to the accurate portrayal of the *dramatis personae*. In a recent monograph⁽¹⁾ I have discussed quite fully the organization of psychiatric care and research in the USSR with an appendix covering the situation in Czechoslovakia. My own report is dry and factual compared with the present paper. Almost all of us who venture into the Eastern European countries and have provided our hosts with any sort of time schedule have been most cordially received. Psychiatrists and other types of researchers have the same sort of time schedule as do most of us. If a psychiatrist whose name was only vaguely familiar to us were to call from a local hotel announcing his arrival and expecting to be entertained and shown the courtesies of our institution "today and tomorrow because we are leaving the next day" one would hardly be expected to drop everything else in order to comply with such a request. This is particularly true if it turned out to be the fifth or the fiftieth one in a row. In other words, for those of you who intend to visit these countries and would like to see the institutions, make certain that plenty of advance arrangements are made.

The only point about which I have to carp is a minor one. At first glance we are somewhat staggered by the extraordinarily high cost of items such as coffee or "luxuries." Translated directly into American monies or even in terms of "how many hours one must work to earn a pair of something or other" there appears to be gross underpayment. It is important to remember that the cost of housing is almost negligible, medical care is provided without cost, pensions and retirement are available at no direct expense to the individual and that provisions for the education of one's children are well taken care of. This means that many of the fixed costs which exist in our own culture are absent. Consequently, the true comparison should be in respect to *disposable income*. The balance is still distinctly in our own favor but not to the same extent as would appear at first glance.

This summer I expect to check on the ac-

curacy of Dr. Masserman's observations about Yugoslavia and in return extend my permission for him to visit Liberia, Nigeria, Afghanistan, *etc.*, so that we may subsequently compare notes. The peripatetic American psychiatrist fulfills a most useful function and this species should be encouraged.

SCRUPULOSITY : RELIGION AND OBSESSIVE COMPULSIVE BEHAVIOR IN CHILDREN¹

WAYNE M. WEISNER, M.D., AND
REVEREND PIUS ANTHONY RIFFEL, S.J., M.A.²

The term scrupulosity is not new and has both theological and psychological aspects. The term scruple is derived from the Latin word *scrupulus*, meaning a small, sharp pebble which when lodged in a shoe caused discomfort or interference with walking. Later on, the term came to mean a very small weight, about one twenty-fourth of an ounce, so small as to affect only the most sensitive balance. From this, the English word scruple came to acquire a moral meaning of a minute reason or motive—so slight as to affect only a very delicate conscience. In this sense it has the dictionary meaning of careful, exact, conscientious, and implies a good healthy meticulousness. In its technical sense (and as used in this paper) the term scruple means an unhealthy and morbid kind of meticulousness which hampers a person's religious adjustment.

Early spiritual writers looked upon continuous scrupulosity as a moral malady of the soul. The past and present theological attitude is that scrupulosity means fear and insecurity which tend to make an individual see evil where there is no evil, serious sin where there is no serious sin, and obligation where there is no obligation. Thus scrupulosity is not seen due to a lack of knowledge but to emotional factors. There is evidence of a disturbance of judgment in that the scrupulous person considers something as important which in reality is trifling and negligible. These result in endless consultations with many priests, a state of endless doubt, and involvement with trivialities, all of this together constituting in varying degree a pathological state.

Among the first to classify the scrupulous person from a psychological point of view was Janet(6). He saw scrupulosity as a manifestation of psychasthenia. Emyieu(4)

followed Janet's theories. Fenichel(5) or more recently Mahoney(7) explain scrupulosity as a result of deep unconscious conflict. They see the scrupulous person as a victim of an over-severe superego. He has the ambivalence associated with regression to an early stage of personality organization and uses the defense mechanism of reaction formation, isolation and undoing, which are characteristic of compulsion neurosis. There are other interpretations by Allers(1), Moore(10) and Mailloux(8).

There is a high incidence of scrupulosity among the Catholic population. In a recent survey by one of the authors(12) it was found that one of 4 sophomores in a Catholic high school admitted to current scrupulosity. One of every 7 Catholic college students admitted to current scrupulosity. There was no sex difference. It must, however, be pointed out that much of this scrupulosity is transitory and not necessarily indicative of severe pathology. The duration ranged anywhere from a few months to 4 years with the average duration somewhere between 1 and 2 years. The age of onset is scattered across the developmental period from early childhood to late adolescence with a marked increase in the frequency of onset during early puberty. Doyle(2), Mullen(11) and McGowan(9) seem to be in agreement with these findings. We might note Wittel's(3) reference to "a phase of the ambivalence in adolescence."

We report here 23 children referred to the St. Charles Child Guidance Clinic, Brooklyn,³ in the past 10 years because of continuous and chronic scrupulosity. The group consisted of 12 boys and 11 girls between the ages of 10 and 17; the mean age being 12 years and 9 months. Fourteen of these children were referred by priests and 6 by doctors. Thirteen were referred specifically for scrupulosity. Typical initial

¹Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

³Much of the clinical material available for this research was due to the interest of the former Medical Director of St. Charles Child Guidance Clinic, Dr. Frank Cassino and the clinic staff.

referrals were : "A bad dose of scrupulosity." "Scruples—most acute anxiety." "Abnormally scrupulous." "Compulsive thoughts of killing mother and beginning of scruples." "Overly religious." "Very disturbed—concerned about right and wrong."

These children were all Roman Catholics whose families were together and practicing their religion. Their primary education was in the local parochial school. For the most part they were of better than average intelligence with IQs ranging from 100 to 135 with only 5 below 110. Scholastically they functioned as well as one would expect from their high intelligence (school averages in the 90's). Furthermore, they were considered exemplary students,* generally receiving A for conduct. Three were "only" children. Typical school reports were : "tops in his class," "fine scholastic record, energetic, splendid altar boy."

On initial referral their mothers were frequently very upset and some were in tears over their child's symptoms. Because of their own anxiety, many of the mothers tended to minimize the symptoms and emphasize the predominantly religious aspect, namely, the scrupulosity which they tended to view in a privileged way. This made it more difficult for some mothers to view it as an illness and consequently follow through on treatment. One of the mothers frequently was or had been scrupulous in the past. We have less information about the fathers, but they usually viewed the condition with less concern.

How did these children show their scrupulosity at the time they arrived at our clinic? Many presented problems concerning food such as : finicky eaters, food having lost its appeal, requiring permission to eat, and it being a sin to eat. Occasionally thumb sucking or hand chewing was in evidence. Breathing also had its problems such as : breathing is a sin, and breathing is stealing the air that doesn't belong to them. Coughing and spitting germs were sinful in terms of possibly killing someone. Another group of symptoms involved obsessive compulsive tics and rituals such as compulsive washing of hands, touching the walls or stepping on cracks, which was seen as a mortal sin. There seemed to be a problem concerning money and handling of posses-

sions. Moving and kicking furniture were sinful as property was destroyed. There was also fear of injuring someone, brushing against someone or killing someone. The sexual area also presented many problems for these children as they were concerned with impure thoughts and mixed parties which had kissing games. There seemed to be over-concern about bodily functions, problems with touching, and in some girls menstruation being equated with sinfulness. One girl felt compelled to take her bath with the light out. Television and other pictures, because of their sexual implications, also troubled some of these children. One penciled in low necklines seen in magazines. There was over-concern about modesty and their dress for fear they might be sexually seductive to others. One girl was concerned lest her parochial school uniform might be too sheer.

How did these children show their scrupulosity in specifically religious behavior? As practicing Catholics many of them not only attended church regularly but went to daily Mass. They were looked upon as good children and more religious than average. There were indecisions about right and wrong and fear of wrong in everything. They were continually consulting the priest and re-examining their conscience frequently throughout the day. The problem about Confession showed itself in various ways and was frequently quite dramatic. They felt past sins were either not properly confessed or were not properly understood by the priest. They were afraid they had omitted something and there were endless ruminations and repetitions of the same sin, and of all the trivial circumstances surrounding their actions, with inability to arrive at a satisfactory decision. Many found it difficult in going to Communion because of their inability to resolve their doubt about sin on their soul. In several cases among our boys it was found that there was much concern and fear about having sold their souls to the devil. One boy sold his soul to the devil so that the Dodgers would win. One girl went into a trance in church on the night she felt she had converted her non-Catholic grandfather because he finally accompanied her to church.

The precipitating event which triggered an acute phase of scrupulosity was an intense situation emotionally linked with their conflict. In our cases we found: A. The introduction of sexual material as, for example, the first mixed party or kissing game; learning about the processes of birth from a friend; seeing dirty words on a lavatory wall. B. Special religious events, such as the beginning of Lent or the making of their Easter Duty. C. A traumatic event such as sudden separation from the mother or mother substitute; or physical injury, or hearing a story about someone being possessed by a devil.

The personality picture of these scrupulous children as presented by the mothers appeared as follows: The children were usually seen as perfectionistic, being over-clean, always prim and fussy, extremely neat. They were also studious and too thorough, spending much time on their homework with a need to excel (which in fact they did). One youngster was described as: "Prays, works and studies intensely for long periods of time." Others were described as being "too good," "always a good child" and "requires little correction." They were described as shy, oversensitive, serious, nervous with a tendency to worry, and depressed. Socially they adjusted poorly and seldom had close friends and thus appeared as withdrawn, seclusive and lonely. The mothers felt that their children were overattached, needed their approval for being good and made them their chief confidantes. However, remarks from the mother on sex and sin were disturbing to them. The mother's feelings and her health also concerned them. In brief, there was very close mother-child relationship and what frequently appeared to be overprotection on the mother's part which resulted in a dependent relationship.

In general, in the eyes of the mother, early developmental history did not seem to deviate too much from the normal. In a few cases there was mention of early operations or rheumatic fever or a kidney infection. Several had asthma, all of which seemed to focus the mother's attention more on the child than on the other siblings. One youngster sucked his thumb until the age of 6, then bit his nails and then began to pull his

hair and then finally, when reprimanded, crossed his eyes and walked into the wall. Unfortunately, information on toilet training was scant. It was seldom specifically mentioned as being difficult. In general, their early behavior was seldom mentioned as a problem.

The personality picture as derived from psychological testing may be summarized as showing much immaturity and dependency. The youngsters appeared introverted, fearful, sensitive, anxious, critical and perfectionistic. They were frequently guarded, evasive and cautious. There was a preponderance of obsessive compulsive traits, lack of spontaneity, and there were indications of rigidity and constricted functioning. Ambivalence and seeking inner controls of emotions were also in evidence. Chronic and acute doubting appeared. Sexual preoccupation, sexual conflict and guilt were strongly indicated. In many there was poor self identity.

Initial psychiatric interviews gave further confirmation of their personalities as described above. In all, 18 psychiatric interviews were available. Nine of these scrupulous children were seen as having an underlying schizophrenic matrix or functioning on a pre-psychotic level.

These children presented a chronic and severe form of scrupulosity. Although the content of their productions was of a religious and spiritual nature, the problem was basically not a moral, but an emotional one. The core problem was in the handling of both sexual and aggressive impulses, and we see the symptoms on all levels of psychosexual development. The aggressive impulses seemed to produce the most difficulty. Much aggression was present but went unrecognized by others and more especially by themselves. The competitive theme was very strong with need to excel, and much sibling rivalry. They were frequently manipulative, passively resistive and provocative. Their sexual conflict had oedipal overtones. Coupled with this was profound and incapacitating ambivalence (mixed feelings) and excessive guilt. They tended to use intellectual defenses at the expense of their emotional development. The defenses met with were the ones common to the obsessive compulsive syndrome:

reaction formation, doing and undoing, denial and isolation. In short, the ego is caught between the forces of the id and superego. In these children their normal healthy drives and inhibitions became exaggerated and out of proportion, and their behavior thus appeared irrational and frequently bizarre and ineffectual. Although not stressed by the mothers, there frequently seemed to be a depressive element with weeping and crying.

Seven boys and 4 girls received treatment at the clinic, generally for one year. However, several children are currently in their second year of treatment. The 4 girls showed improvement as did 4 of the 7 boys. Of the other 3 boys, one showed uncertain improvement with poor prognostic expectations at the end of treatment. Another schizophrenic boy had to be hospitalized and the third boy, seen on periodic consultation over a number of years, remained unchanged. Treatment was usually on a supportive level. Their defenses were seldom, if ever, directly attacked. Much of the progress in therapy was due to the relationship established and the scrupulosity itself did not become much of an issue in their treatment. Medication: Thorazine, Compazine or Miltown, was occasionally used to tide them over their acute episode. However, initial psychotic episode, if any, was short lived and quickly dropped. They were usually able to wall off this episode.

From treatment as well as follow-up studies we see that the children were usually able to continue to function and make a fairly adequate adjustment. The recent follow-up study in which 17 of the scrupulous children were contacted, showed that they continued in high school or have graduated. Six are presently in college, and most of them continue to function on a better than average academic level. Two of the girls are married and one boy has just returned from 2 years in the army. Of 4 girls, one is a stenographer, one a typist, one an accountant and one a bookkeeper. The mothers of these youngsters still have difficulty in seeing their children's scrupulosity as an emotional problem. Many of these children still have difficulty in making a comfortable social adjustment.

SUMMARY

In this paper, a clearer picture of severe chronic scrupulosity as a pathological condition is presented. Children actually referred to a child guidance clinic for their scrupulosity are seriously disturbed. What became clear to us was that the scrupulous children presented a consistent picture in terms of symptoms and underlying personality traits. It usually appears as an obsessive compulsive disturbance involving fears and doubts. However, the constriction and inhibitions of these scrupulous children were frequently indicative of a schizoid personality and, in some instances, of an underlying schizophrenic matrix. This consistent picture of the scrupulous child which emerged from our research, enabled us to obtain a more immediate and fuller understanding of any new child referred to our clinic for his scrupulosity, and to work with the scrupulous child in a more confident and effective manner.

ADJUSTMENT OF EIGHTY DISCHARGED GERIATRIC-PSYCHIATRIC PATIENTS¹

MORSE P. MANSON, Ph.D., AND CARLTON L. ENGQUIST, M.S.W.²

It is felt by professional workers in medicine, psychology, nursing, social work and rehabilitation, that older patients encumbered with severe physical and psychiatric illnesses, as are many of the chronic patients in the Veterans Administration Hospitals, have little chance of returning to family and community living, *unless they are provided with the appropriate professional assistance, carefully prepared, and consistently helped to adapt themselves to some form of community living.*

The validity of the belief that chronically ill, geriatric-psychiatric patients, receiving appropriate assistance could make satisfactory and satisfying adjustments outside an institutional setting was subjected to critical analysis in this study.

At the VA Hospital, Sepulveda, California, a 100-bed geriatric-psychiatric service has been in operation since 1955. Initially the staff, because of the complexity of their patients' problems, had many reservations concerning the ability of these long-term geriatric-psychiatric patients to adjust to settings other than chronic hospitals. In November, 1957, the treatment program was intensified and increased emphases were placed on more active therapeutic and rehabilitation techniques. Eighty patients were discharged. The follow-up study concerns these 80 patients.

GROUP CHARACTERISTICS

All were males, veterans, and formerly patients in the above geriatric-psychiatric service.

Age: The age range for the group discharged was 26-82 years; the mean age was 62.3 years.

Race: The discharged group was 99% white and 1% non-white; the remaining group was 95% white and 5% non-white.

Marital Status: Marital status percent-

ages of the discharged and remaining groups showed one significant difference at the .01 level of confidence: a larger number of divorced men were in the discharged group than in the remaining group.

Number of Diagnoses: The mean number of diagnoses of the remaining group was 2.4: that of the group of discharged patients was 2.0.

Diagnoses: Of the discharged patients, 85% carried a diagnosis of "psychosis"; 35% had "chronic brain syndrome"; 13% were considered "incompetent"; 11% had "cardiovascular disease"; 8% "pulmonary disease." The remaining group had significantly larger percentages of patients with "chronic brain syndrome"; "cardiovascular disease" and "tuberculosis-inactive."

Time in Hospital: The discharged group had spent an average of 21.7 months in the hospital as compared with 26.3 months for the remaining group. The majority of these patients had been hospitalized elsewhere prior to admittance to this hospital. For example, of the 22 patients who had accepted family care placement in this study, 14 had been hospitalized over 10 years. Of this group, 9 had been hospitalized over 20 years; while 4 had been hospitalized over 30 years.

Number of Discharges: The mean number of discharges in the remaining group was .1; that of the discharged group had been 2.0. *Thus the discharged group had received 20 times the number of discharges which the remaining group had received.* It is, of course, obvious that the men in the remaining group were much sicker than those in the discharged group, nevertheless the question arises: Could more discharges have been provided the remaining group, thus exploring the feasibility of living outside the hospital?

Death rate: A comparison was made of the death rate of the 2 groups. The death rate of the discharged group over a period of 44 months was 8%; the hospitalized group had a death rate of 18% over a 39

¹ From the VA Hospital, Sepulveda, Calif.

² Respectively, Chief, Counseling Psychology Services, and Chief, Social Work Service, VA Hospital, Sepulveda, Calif.

month period. Converted to death rate per month this would be .18% of the discharged group and .46% of the remaining group per month.

Number of Places Lived in Since Discharge: Of 67 returns, 43 discharged patients or 66% remained in the original home developed through hospital discharge planning. Thus a large percentage of the total discharge group of 80 patients—at least 53%—adhered closely to the discharge plan developed in the hospital.

Sources of Income: Fifty-three patients indicated definite sources of income. Only 5 questionnaires indicated no source of income. These data show that a large percentage of discharged patients had economic resources available. In a few cases, income was sufficient for full maintenance costs.

Average Monthly Income: Forty-seven returned questionnaires presented the monthly income of discharged patients. The mean monthly income for this group was \$155.00.

Adjustment to Present Living Situation: Ratings were made by the interviewers of adjustments made to patient's present living situation. The scale used included 4 ratings: poor, fair, good, and excellent. Based on a point system of 1-2-3-4, the mean rating for this group was 2.3 closer to "fair" than "good."

Adjustment to Present State of Health: The mean point evaluation was 2.7, somewhat closer to the "good" rating than to the "fair" rating.

Is Patient Receiving Outpatient Medical Care? "Yes" responses to this question was 26%, "No" responses was 74%. When hospital staff was queried regarding the percentage of patients discharged from the geriatric-psychiatric service who would require medical services after discharge, responses ran from 70% to 95%. The finding that only 26% were receiving medical treatment was surprising to nearly all staff members.

Adjustment to Work or Hobbies: The mean point rating was 2.3, closer to "fair" than to the "good" rating.

Is Patient Working? Responses were "Yes" for 33%. It was surprising to find that one-third of these discharged patients were

working, since it was the belief of most hospital staff members that not more than 10% could or would return to work, even to marginal types of work. Not all of those working were receiving wages. It is believed that at least 8 of the 16 working were being paid.

Since the average number of hours worked by each working patient was 19.5 or 975 hours for a 50 week year, it is estimated that a working patient earning the federal minimum wage of \$1.00 per hour, would earn \$975.00 per year. The group of 16 working patients then would earn \$15,600. Since only about 50% of the working group is being paid, the group is earning approximately a minimum of \$7,500 per year.

If Working—what does he do? The 16 discharged patients were engaged in 11 different jobs. In this group were 4 men who worked 8 hours per day, 5 days a week. These findings are very encouraging and point to potentialities within men who present complex geriatric-psychiatric histories.

Adjustment to Social Activities: The mean rating was 2.3, closer to "fair" than to "good."

In Your Opinion Does This Patient Need Hospitalization at This Time? Ninety-three percent answered "No" and 7% answered "Yes." This finding indicates that adequate hospital services had been provided to these discharged patients. It also suggests that living outside a hospital has salutary effects.

What Additional Services Would Improve or Stabilize This Veteran's Adjustments? On the 31 questionnaires which dealt with this question, there were 41 responses. The largest single response—12 or 29%—was "None."

How Long Do You Believe Patient Will Remain Out of Hospital? Eighty-two percent stated patients would remain out of the hospital "Indefinitely."

What Might the Veterans Administration Hospital at Sepulveda Have Done to Make This Patient Better Able to Remain Out of Hospitals? The largest number of responses—23 or 63%—answered "Nothing."

DISCUSSION

A significantly greater percentage of divorced men were included in the discharge group. It is heartening to note that in this group, 6 were over the age of 70 years, and 2 were in their 80's. Approximately 60% were living in protected settings and receiving continued supportive case work help by the hospital or Regional Office social workers.

The discharged group had a mean of 2.0 medical diagnoses. Of these, 85% had been diagnosed as "psychotic" and 35% with "chronic brain syndrome." Being psychotic does not significantly affect hospital discharge. However, brain damage does significantly reduce the possibility of leaving a hospital. The group remaining had approximately twice the incidence of brain damage of the discharged group. There appears to be evidence that cardiovascular disease and tuberculosis (inactive) reduce the chances of leaving a geriatric-psychiatric service. The combination of brain damage, cardiovascular disease, and tuberculosis (inactive) suggests that the older patients who require considerable physical attention have fewer chances of making acceptable adjustments outside the hospital than do patients with minimum physical needs but with psychoses. In further support of this observation, experience in this hospital shows that the geriatric-psychiatric patient returns to the hospital in the majority of cases for medical reasons rather than for psychiatric conditions, even though he may have been originally hospitalized for psychiatric reasons.

A psychotic patient who can provide self-care is much more acceptable to his family or other families than is the non-psychotic who needs personal physical attention. This conclusion is strengthened by noting that even the classification of a patient as "Incompetent" does not affect discharge possibilities: 15% of the remaining patients were considered as incompetent against 13% of discharged patients.

The discharged group had an average of 4.6 months less hospital time than did the remaining group.

On the average, the discharged group had received 2.0 discharges, while the remaining group had received .1 discharges, and 88%

of the remaining group never had received a discharge. The subject of hospital discharges calls for further research. It is highly desirable to explore intensively new approaches to discharges and different kinds of discharges, particularly for patients who require limited physical care.

Greater community involvement in the treatment of geriatric-psychiatric patients is needed so that more of these patients have opportunities for leaving the hospital, even for short periods, to meet with non-patient groups, and engage in community activities whenever possible.

An analysis of the death rate was made to determine if there was justification for the beliefs of some that exposure of these geriatric-psychiatric patients to the outside world would prove dangerous. The 8% death rate for the discharged patients as against the 18% death rate of remaining patients *per se* indicates that being discharged does not increase the incidence of death.

One of the several encouraging findings was the movement of these discharged patients into 30 different communities. Sixty-three percent of the discharged patients settled in the Los Angeles or San Fernando Valley, within close reach of the hospital.

About one-third of the discharged group was living with its immediate family, while over one-third was living with foster families. Thus over two-thirds of the discharged group had returned to family settings, rather than to institutional settings or to living by themselves. For most of these patients a return to a family setting was a realistic goal.

Another encouraging finding was the stability of the discharge plans developed within the hospital setting. Of the 67 returned questionnaires with data regarding the number of places lived in since hospital discharge, 44 or 66% indicated no moves had been made and the discharged patient was living in the home or setting developed with him while he was hospitalized. This finding points to the importance of the social worker in laying the groundwork for realistic discharge plans with responsible family members and the patient.

Perhaps the most unexpected findings were those dealing with health, medical

care, and the need for hospitalization. The greatest amount of concern and uncertainty on the part of the staff existed in these areas. The findings of this study, however, point clearly to the ability of these discharged patients to maintain their well-being and even reduce the amount of medical services they once had required.

Only 26% was receiving outpatient medical care. Only 7% seemed to be in need of further hospitalization at the time of the interview.

Considering the type of patients composing the discharge group, it is encouraging to discover their ability to maintain themselves relatively free of direct medical or hospital service. The conventional belief is that geriatric-psychiatric patients require long-time and extensive medical-psychiatric attention. Because of this belief, movement of such hospitalized patients often is retarded by excessive concern over discharge planning, and resistance to moving them. In many cases, the potentialities of such patients are grossly minimized or completely disregarded.

It is well-known that the geriatric-psychiatric patient, after long-term hospitalization, develops strong resistances to change or movement; this is especially true when he is faced with leaving the protected environment of the hospital to return to community living, which he often looks upon with doubts and fears. Careful discharge

planning, which includes the patient at each step of the way, enables the patient to accept, often on a trial period, living outside the hospital.

Experience points out that the chronic patient who has had an opportunity to live outside the hospital, even for a short period, has a better chance for developing and carrying out sound discharge plans which will keep him out of a chronic hospital than has the patient who has never made such an attempt.

In view of the above findings, resistance to the movement of geriatric-psychiatric patients from a hospital setting to a home or community setting, in many instances seems to be unwarranted, and actually anti-therapeutic. Where limited movement of patients exists, a definite need for greater effort in the development of realistic discharge plans seems indicated. Limited movement of patients often suggests that staff members are in need of training and clarification of treatment objectives.

In brief, these findings indicate that the discharged group of geriatric-psychiatric patients was happier, healthier, more productive, more gainfully employed, and more active socially than when hospitalized. Life outside the hospital stimulated these men to live fuller lives and reduced their medical needs. Life outside a hospital appears not to have increased the death rate for this group.

SOME PSYCHOLOGICAL ASPECTS OF ISOLATED ANTARCTIC LIVING¹

CAPTAIN CHARLES S. MULLIN JR., (M.C.), U.S.N.²

When Byrd went to the Antarctic in the twenties he is said to have taken along, in addition to two coffins, an even dozen strait jackets. This pessimistic precaution turned out to have been unnecessary, but does suggest the respect that even experienced explorers have had for the psychological vicissitudes of isolated polar living. To be sure, conditions at isolated United States I.G.Y. Stations in the Antarctic are different from the time of the early explorers. There is less danger and hardship, better communication with the outside world, and (possibly) better selection of personnel. (At least there is more psychological professionalism applied to the problem of selection today.) Nonetheless, for most individuals the business of living for a year in an isolated polar station still makes serious demands on adaptive resources.

Here is the situation. A small (12 to 40) group of volunteers of widely varying interests and backgrounds (scientists, officers, and enlisted personnel) are thrown together in close personal association and isolated from all other society for a large part of a year. Most of life is lived indoors except for the lucky few who may go out on "traverses." For 7 or 8 months of the year, there is no communication with the outside world except by radio, and for several months of the winter there is 24 hours of darkness. During this time the physical milieu, the routine of life, and the small exclusive society is, of course, characterized by an inevitable sameness and monotony.

There is much interest these days in the psychological effects of isolation, in part perhaps, because of current fantasies about space travel and planetary exploration. Accordingly, this review of effects of voluntary

isolated group living, in a non-experimental situation, may be of interest.

The present study was based on interviews conducted "on the ice" with some 85 personnel who were nearing the end of their wintering-over period at a number of smaller, more isolated stations. The interviews were conducted by 2 psychiatrists and 2 psychologists, during two visits to the Antarctic on successive years. The interviews lasted from one to several hours, and in many instances the subjects were interviewed separately by two members of the team. The goodwill and frankness of the interviewees was impressive. In some instances there was a mild initial xenophobia, but this was invariably quickly replaced by a spirited degree of cooperativeness that in many cases suggested a compulsive eagerness to communicate.

OBSERVATIONS

1. *Danger, Hardship and Cold.* Danger, hardship, or the direct effects of cold did not represent important stresses. Indeed, the absence of much hardship and danger, and the relative luxury of living conditions, were sources of considerable disappointment and disillusionment for many of the younger and more romantically inclined members.

2. *The Main Stresses.* The major stresses appeared to be: (a) The problem of individual adjustment to the group, (b) the relative "sameness" of the milieu, and (c) the absence of many accustomed sources of emotional gratification. Undoubtedly, it was the interaction of these stresses that produced the effects observed: but, in the production of a given effect, one of these classes of stress might be more determinant than another.

3. *Hostility.* We were impressed by the relative absence of overtly expressed hostility. At most of the smaller stations visited, fights and angry arguments were remarkably rare, considering the conditions of living described above. Group and individual tensions and irritations are ever pres-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Medical Department, U. S. Naval Academy, Annapolis, Md.

ent, but the most important lesson a wintering-over man learns is that he cannot afford to alienate the group; that in this tight little society he is dependent in large measure upon the goodwill of the next man and of the group as a whole for his vital feelings of security, worth and acceptance.

4. *Headaches.* Probably related to this phenomenon of controlled aggression was the rather extraordinary frequency of headaches, since it is generally assumed that there is often a relationship between "inadequately" expressed hostility and the occurrence of headaches, and since no primarily physical cause could be ascribed. It was interesting that these headaches seemed to affect the officer-civilian group more than the enlisted contingent. The enlisted men had various ways, acceptable to the group, for expressing their hostile-tensions, for example: vigorous horseplay; loud complaining without too much rancor; swearing; and an interesting technique of exchanging insults, often quite personal and to the point, but rarely reacted to with much, if any, anger, as if there were a tacit mutual recognition of the function of the exchange. The more sophisticated officer-scientist group were both more limited in the effective techniques available and were perhaps under a greater self-imposed necessity for careful control of their aggression; hence their preponderance for headaches.

5. *Insomnia.* Varying degrees of sleeplessness was a fairly wide-spread phenomenon, but confined almost exclusively to the dark winter season, rather than to the summer period of 24 hour brightness. It affected men who had never before had difficulty in sleeping. At one small New Zealand Station, everyone in camp was a member of the "Big Eye" Club. The only qualification for membership was insomnia. The rules of the club were simple. You were expected to retire, but if efforts to sleep were unsuccessful, you could then join the club session in the common room, sitting about reading, chatting, playing cards until you felt sufficiently tired to try the sack again. The causes of the "Big Eye" (the term widely used in the Antarctic for the insomnia problem) are not entirely clear, but seem related to such factors as the ac-

cumulation of group and personal tensions, the reduced physical activity of the dark winter period, and group suggestibility. Some men commented that although they felt tired, even exhausted, at the same time they felt restless and unrelaxed when they endeavored to find sleep. Several researchers (1, 2) have observed that a more or less intense desire for stimuli and action is an effect of the experimental isolation experience. Perhaps a conflict between a desire to sleep and a need for action has some bearing on the "Big Eye" problem.

6. *Intellectual Inertia.* There was a curious and widespread lack of intellectual energy which was manifested most severely during the months of winter, i.e., after several months of isolation. The majority of personnel had come to the Antarctic planning to carry out certain "extra-curricular" projects. The intention might be to learn a language, do some "serious" reading, accomplish batches of correspondence courses, write articles, learn to play a musical instrument, etc. Rarely were the original plans realized; and, in the majority of instances, although there was plenty of time available, very little was done in the direction of even making a good start on the project. Although reading was a fairly widespread spare time occupation, usually the class of reading done was of a "lower" order than that characteristic of the individual's usual interests and taste.

7. *Impaired Memory and Concentration.* Akin to the phenomenon of intellectual inertia was the finding of impaired memory, alertness and concentration. This was again manifested most obviously during the winter. Many were not appreciably affected, but at one isolated station this impairment of memory and mental acuity affected about one-third of the camp in varying degree, from unwonted absentmindedness to the occurrence of mild fugue states. Impairment of mental acuity and the capacity for sustained mental effort has been noted by many observers in isolation experiments in the laboratory (1, 2). It is probable that the intellectual anergia and impaired alertness reported here bear some relationship to the factor of prolonged exposure to "sameness"—the same few faces and personalities, the same limited physical milieu, the same rela-

tively simple routine of life—plus a long period of limited physical activity and mobility; or, in short, the effect of the reduction in the amount and variety of meaningful sensory stimulation over a prolonged period of time.

8. *Appetite.* As might be expected, "oral" needs were enhanced, presumably because of tensions that could not be readily expressed, and because of the absence of other basic gratifications. Appetite and consumption were enormous, and weight gains of 20 or 30 pounds during the year were not unusual. When the cook was adequate to the challenge, his prestige was of course enormous.

9. *Sexual.* It is axiomatic that no area of human functioning is more subject to distorted reporting, exaggeration, suppression and repression than the area of sex, and the following observations are based, of course, largely on what we were told by the men. However, it appears that these generalizations may have some validity. Isolation from women was not, in itself, a serious problem; or, more accurately, was not a matter of conscious yearning, erotic or otherwise, except perhaps for a very few individuals very early and very late in the year, or in a few instances during periods of personal emotional stress. With respect to sex dreams, nocturnal emissions and masturbatory activity, the following impressions were gained: (a) There was a slight general tendency to increased frequency; (b) this increased frequency was more apparent during periods of relative inactivity and personal emotional stress, and towards the end of the tour (the question of reawakened fantasies). With respect to evidences of inversion trends, there were no indications of any overt homosexual practices, scandal, or gossip, although, as might be expected, there were indications here and there of mild covert manifestations throughout the group. For one thing, privacy was at a premium. But, perhaps more importantly, the "risk" to the vital need for group acceptance was too great.

10. *The Absence of Usual Sources of Emotional Gratification.* For the group as a

whole, nostalgia was not a problem, as a felt experience; and separation from home, wife, family, and familiar situations of the man's personal "civilization" was rarely a subject of any serious continuing preoccupation. However, most agreed that the absence of these supportive influences increased the burden of their adaptation. As already indicated, the evidence suggested that sexuality was repressed and substitutive oral satisfactions were ascendent. On the other hand, for a few men it was obvious that separation from home, wife, children, and family responsibility, meant for them the subtraction of an element of stress in their personal adjustment.

11. *"Long-Term" Effects of the Experience.* A few "old salts" and a few scientists who had previous isolation experience felt that they had experienced no great changes within themselves. However, the majority felt that something good had happened to them that they hoped and believed would endure. This was expressed in various ways, as for example, more self-discipline, greater adaptability, more tolerance, more patience, more understanding of self, and more understanding of the other man. However, not one man interviewed was unambiguously desirous of repeating the experience.

SUMMARY AND CONCLUSIONS

Some psychological effects of isolated group living in the Antarctic are described. It would appear that the cold, danger, and hardship are not major stresses. The most important psychological stresses appear to be: First, the problem of individual adjustment to the group; second, and more subtly acting, the relative "sameness" of the milieu; and third, the absence of certain accustomed sources of emotional satisfaction.

BRIEF OBJECTIVE MEASURES FOR THE DETERMINATION OF MENTAL STATUS IN THE AGED¹

ROBERT L. KAHN, Ph.D., ALVIN I. GOLDFARB, M.D.,
MAX POLLACK, Ph.D., AND ARTHUR PECK, M.D.²

In the process of conducting a survey of institutionalized aged persons for the Office of the Consultant on Services for the Aged,³ it became evident that the problem of mental disorder in this population was related to organic brain damage. For this reason, it was considered desirable to develop brief, objective, and quantitative measures of mental functioning related to cerebral impairment. The purpose of this paper is: 1. To describe the procedures that were utilized, 2. To explain their rationale, 3. To show the results obtained to date, with particular reference to their validity, and 4. To indicate the potential further usefulness of these procedures.

METHOD

Two psychological tests were used in this study, the mental status questionnaire (MSQ) and the face-hand test.

The Mental Status Questionnaire: This consisted of a series of 31 questions covering such areas as orientation, memory, calculation, and general and personal information. These questions were drawn partly from standard mental status examination procedures, and partly from recent special investigations of patterns of altered behavior with cerebral dysfunction(1).

¹ Presented at Downstate Interhospital Conference, New York State Department of Mental Hygiene, March 29, 1960.

² Respectively, Research Psychologist, Consultant, Research Psychologist and Research Psychiatrist, Office of Consultant on Services for the Aged, Queens Village 27, N. Y.

³ Sampling procedures for the survey were planned and supervised by Julius A. Jahn, Ph.D. Research activities were coordinated by Helen Turner, M.S., with the assistance of Syra Cohen, B.S. The psychiatric examinations were done by Kenneth Altshuler, M.D., Morton Aronson, M.D., Martin Barad, M.D., Arthur Peck, M.D., Vincent Squilla, M.D., and Robert Shapiro, M.D. Physical examinations were made by and under the direction of Isadore E. Gerber, M.D. The epidemiological aspects of the study were coordinated by Israel Gitlitz, M.D. We are grateful to the hospitals and the homes who participated in our survey and who made our studies possible.

From the total questionnaire, 10 items were selected as the most discriminating and used for the quantitative determination of mental status. These items were: 1. What is the name of this place? 2. Where is it located (address)? 3. What is today's date? 4. What is the month now? 5. What is the year? 6. How old are you? 7. When were you born (month)? 8. When were you born (year)? 9. Who is the president of the United States? 10. Who was the president before him?

While these questions themselves are familiar enough, our procedure insured that the same questions, worded in the identical fashion, would be asked of everybody. Secondly, by obtaining a score based on the number of errors in response to these 10 questions, a quantitative index of mental functioning was provided.

The Face-Hand Test: This test was first described by Fink, Green and Bender(2) as a diagnostic procedure for brain damage. The test consists of touching the patient simultaneously on the cheek and on the dorsum of the hand, and asking him to indicate where he was touched. Ten trials are given: 8 face-hand combinations divided between 4 contralateral (e.g., right cheek and left hand) and 4 ipsilateral (e.g., right cheek and right hand) stimuli, and 2 interspersed symmetric combinations of face-face and hand-hand. After the second trial, if the patient only reports one stimulus, he is asked, "Were you touched anywhere else?" in order to give him the concept of twoness. If the patient fails consistently to locate both stimuli correctly within the 10 trials, he is classed as positive. The main types of errors are extinction, in which only 1 stimulus is indicated (almost always the face), and displacement, in which 2 stimuli are indicated but 1 of them, generally the hand stimulus, is displaced to another part of the body (e.g., if the person indicates both cheeks when the face and hand were actually touched). A patient is

rated negative if he is consistently correct within the 10 trials. Frequently he makes an error on the first 4 trials, but is consistently correct after perceiving the 2 symmetric stimuli.

The face-hand test was first given with the eyes closed and then, if the individual showed a positive reaction, was repeated with the eyes open. Since it was found that in about 90% of the cases the response under the two conditions was identical, the response with eyes open has been used in our analysis of data.

The face-hand test was considered a desirable procedure for this survey, not only because of its established value as a test for cerebral dysfunction, but also because it is relatively "culture free," being an unlearned perceptual task. It has the further advantage of being usable with patients who don't speak English very well or present some other problem in verbal communication.

POPULATION

The population sampled consisted of 1,077 patients residing in homes for the aged, nursing homes and state mental hospitals located in New York City. The individuals included were those who were 65 years of age or over at the time of first admission to the institution, and in residence as of a given month during the survey period of March to November, 1958.

Both the institutions chosen for study and the persons tested within each institution were selected by random sampling. All 3 state hospitals in New York City were sampled, with a total of 169 patients examined. Of the 102 proprietary nursing homes registered by the Department of Hospitals in January, 1956, samples were drawn from 13 and 426 persons examined. Nine of the 49 homes for the aged listed by the Community Council of New York City in 1957 were sampled, with 482 residents examined.

PSYCHIATRIC EXAMINATION

Each person was also examined by a psychiatrist within a 1 month period of the psychological examination. The psychiatrist, on the basis of a conventional psychiatric interview, assessed each person for the

presence and degree of chronic brain syndrome, the presence or absence of psychosis associated with chronic brain syndrome, the presence of other types of psychiatric disorders, the degree of management problem, and whether or not the person was certifiable.

RESULTS

1. *Chronic Brain Syndrome.* There was a marked relationship between the psychiatrists' evaluations of the presence and degree of chronic brain syndrome and the results of the two psychological procedures.⁴ Ninety-four percent of those making no MSQ errors were rated as having none or mild chronic brain syndrome. In contrast, of those with 10 MSQ errors, only 5% were rated as none or mild, and 95% were considered to have moderate or severe CBS. Between these two extremes there was a linear progression, with increasing number of errors associated with more severe CBS rating.

The results are similar for the face-hand test. Seventy percent of those negative on this test were rated as none or mild CBS; a similar rating was given to only 27% of those who were positive.

2. *CBS with Psychosis and Certifiability.* There was a relationship between the psychiatrists' ratings of psychosis in association with CBS and of certifiability to the psychological tests. Of those making no MSQ errors only 3% were rated as CBS with psychosis, in contrast to 75% of those making ten errors.

The certifiability ratings follow the same pattern, with 5% of those with no errors evaluated as certifiable, with a gradual increase with increasing error scores until of those with 10 errors 89% were so rated.

A similar relationship was shown with the face-hand data. Of those who were negative on this procedure, only 13% were rated as CBS with psychosis and 21% as certifiable. Of the patients who had positive face-hand responses, 50% were considered to have CBS with psychosis and 65% certifiable.

3. *Management Problem.* In their evaluations, the psychiatrists included a rating of degree of management problem, none, mild, moderate or severe. Although a large ma-

⁴ Tables and further data may be obtained from the authors on request.

jority of the patients were rated as none or mild, a relationship was still noted between the MSQ and face-hand test results to the management rating. Of those patients with no MSQ errors, 94% were rated as none or mild management problems. This figure declines with increasing error score, until with a maximum of 10 errors only 52% were so rated, with 48% considered to be moderate or severe problems. On the face-hand test, 67% of those with positive response were rated as no or mild management problems, compared to 83% of those with negative results.

DISCUSSION

These results have shown that the mental status questionnaire and the face-hand test are highly related to psychiatrists' evaluations of the presence and degree of chronic brain syndrome, the presence of psychosis associated with chronic brain syndrome, the certifiability status of the patient, and the degree of management problem.

In a sense, these results establish the validity of the psychological procedures as measures of mental status, using the psychiatrists' ratings as the validating criteria. But it is necessary to keep in mind that the psychiatrists' ratings are more subjective, and with considerable variation in the ratings of different psychiatrists examining similar populations. The 2 psychological procedures, in contrast, provide an objective basis for uniformity of observation and evaluation by different observers.

While there is no doubt that other objective or standardized tests could be adapted or devised which would also be correlated with psychiatric evaluations, the MSQ and face-hand test have the advantage of requiring little time for administration. The brevity and objectivity of these tests also make them desirable procedures for rapid clinical screening and for research purposes. For example, we have already reported a relationship between physical functional status and mental status, using either the face-hand test or the MSQ as the index of mental functioning(3). In another investigation under way of prognostic factors in the institutionalized aged, it has been found that performance on both of these procedures is significantly cor-

related with mortality within a 1 year follow-up period.

We would also like to point out certain limitations of these procedures. They are most useful for eliciting mental change associated with chronic brain syndrome, but are very limited in picking up other kinds of psychiatric disorders. Secondly, the tests measure the behavioral pattern at the time of testing and thus may fail to show impairment in patients with fluctuating mental status.

SUMMARY AND CONCLUSIONS

1. Data are presented on a random sample of 1,077 persons residing in homes for the aged, nursing homes and state hospitals in New York City, who were 65 years of age or over at the time of first admission. Each person was examined by a psychiatrist using a standard interview technique, and by a psychologist who administered two brief tests: the face-hand test, and a 10-item questionnaire testing orientation and recall of personal and general information.

2. The results of both tests were highly related to psychiatrists' clinical evaluations of the presence and degree of chronic brain syndrome, the presence or absence of psychosis associated with chronic brain syndrome, opinion as to certifiability, and degree of management problem.

3. It is concluded that the face-hand test and the mental status questionnaire are valid measures for the determination of mental status in the aged, particularly for disorders associated with cerebral damage.

4. These tests are considered to have a considerable potential clinical usefulness for rapid screening purposes. They provide an objective basis for uniformity of observation and evaluation by different observers. The brevity and objectivity of these tests make them desirable procedures for research purposes.

PRESENT DAY CONCEPTS IN NURSING SERVICE ADMINISTRATION IN HOSPITALS FOR THE MENTALLY ILL¹

GRANVILLE L. JONES, M.D.,² AND ANGIE F. WALDRUM, R.N., B.S.³

Ever since that forgotten day, probably in the Old Stone Age, when some sick or injured friend was made comfortable, fed and protected while he recovered, the practice of nursing has attracted attention. It has grown from a simple individualistic endeavor into a highly complex and technical profession. With the revolutionary changes in mental hospital practice in the last decade or two, much more is being expected of nursing than ever before. Furthermore, despite a substantial increase in nursing personnel in the last 10 years, most of our mental hospitals are still far below the minimum standards of the American Psychiatric Association (10, 13). It is evident that we do not now have, and will not have in the discernable future, enough people in our hospitals to do our job properly, if traditional methods and practices continue. It is imperative, therefore, that we utilize the personnel we have much more fully and efficiently than we have been doing. It is because of a conviction that administrative organization and practices can contribute to this end that this paper is being presented.

THE NATURE AND PURPOSE OF ADMINISTRATION

To some professional persons, administration is viewed as something apart from professional practice, something a little less worthy of one's time and attention, something to rebel against and resist (3). This should not be. Administration properly understood, is an extension of our professional arms. It has been defined as "the integrating factor in group effort," (4) as "the marshalling of resources to accomplish a purpose" (1). With special application to

nursing service, it could be described as "a co-ordinated system of activities which provides all facilities necessary for the rendering of nursing care to patients" (1). With the modern American genius for division of labor and for organization, it is not surprising that in recent years a vast amount of time and attention has been spent on the problem of administration.

A recent report, in speaking of hospital administration, states that it

Demands a recognition of the human element and an awareness and appreciation of the attitudes, motivations and incentives in other people . . . a leadership skill in persuasion and adjustment which maintains control while permitting and encouraging individual expression and participation (4).

This description is not peculiar to the hospital administrator but applies with equal force to the nursing administrator. The nurse, by virtue of her position, is in between the patient, the physician, the public and other personnel and must perform many functions with an independent skill on demand by others who set the time and place and indicate the objectives.

It has been said that the philosophy and practices in any mental hospital reflect the personality and attitude of the superintendent. The selection, indoctrination and training of the staff and key personnel give the superintendent the opportunity to build an organization sympathetic toward his own ideas (3). However, the day of the "one man show" is rapidly disappearing. The administrator must still make the decisions, but modern concepts have made it important for all personnel to have an opportunity to participate in the formulation and statement of the philosophy, objectives and standard practices, and to advise on execution and action.

The Superintendent of Nurses in turn sets the climate through which nursing personnel will either be "people-centered" or will be "self-centered." The methods used in

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

³ Chief, Nursing Service, Consolidated Veterans Administration Hospital, North Little Rock Division, Little Rock, Arkansas.

getting things done through people are the responsibility of the Superintendent of Nurses. In the process of organizing, the contribution of each member is properly identified and defined in terms of functions(5,7,8). Organizational planning is a distinct component of management, but once accomplished should not be regarded as fixed or final. If we stay "people-minded," new responsibility, changing work loads and new therapeutic programs in medicine have implications for nursing which may affect even the basic organizational structure. No amount of budget, additional equipment and supplies, procedural changes or personnel can completely offset faulty organization.

The administrator of nursing service must have faith and confidence in the nursing personnel through whose development nursing will improve(9). Problems are solved through consultation with the workers concerned rather than by the issuance of mandates. The persons to be affected are given the opportunity to participate in formulating plans. This technique facilitates change, has a maturing effect on human relations and is a motivating influence for all personnel toward an efficient and enthusiastic accomplishment of their jobs.

The nurse administrator must be willing and able to delegate authority to the appropriate level, to grant the right to plan and act without interference. This does not mean giving up control. Controlling is made up of two elements, organizational structure and supervision. Controlling requires good supervision but not necessarily centralization of authority. It most certainly requires proper delegation of authority and assignment of responsibility. It includes sound organization structure; which makes it possible for groups to work together as effectively as the individuals would work alone.

To restructure the administrative organization from the traditional to the creative and permissive type requires time, tolerance and confidence. It requires remotivation, re-emphasis of individual values and continuous review of present day philosophies of patient care.

In building this democratic organization, the administrator has the responsibility of

interpreting this plan so as to make it possible for each to play his role in implementing the plan. A democratically run structure does not mean a structure without leadership. The following expresses this point

Leadership need not be authoritarian. A leader can assist in defining goals without categorically imposing them; he can discuss alternative methods of proceedings without ordering them; he can encourage spontaneity and individual difference without fostering anarchy; he can give support and approval without creating dependency(2).

NURSING SERVICE ADMINISTRATION

A PART OF THE WHOLE

Nursing service does not function in a vacuum but is an integrated part of the whole hospital program. Nursing is a part of medical care and the nursing care goals must be in line with other medical goals for patients. However, effective care of patients also requires cross communication, planning and co-ordination with other hospital departments, such as: supply, engineering, personnel, housekeeping, registrar. The nurse administrator is a part of management and participates in setting philosophy and objectives. She projects needs for adequate budget for personnel, supplies and equipment. She anticipates needs in the expansion of service. She is responsible for evaluating the program and reducing and controlling costs accordingly. She may be a member of a co-ordinating committee which plans and co-ordinates hospital activities(1, 2, 3).

Today a large portion of the patients are on full or partial privileges and our program of activities is a complex and ever-changing problem. Nursing service is concerned with the patient 24 hours a day and of necessity must co-ordinate its activities with those of the medical staff, physical medical rehabilitation personnel, special service personnel and others, all demanding the time of the patient. Unless careful planning is done by the co-ordinating committee, the patient may find himself moving about solely for the convenience of personnel(6, 11, 12).

The National Joint Commission for the Improvement of Patient Care has recommended that hospitals set up patient care committees, to be composed of mem-

bers of medical staff, nursing staff and hospital administration. Equally important is representation from dietary, admitting, social service. These and other departments may not always be regular members but should be invited to attend when matters are discussed that concern their departments.

Following this same pattern, nursing service may organize a Nursing Care Committee which functions similarly to the Patient Care Committee to bring the planning directly to the personnel on the nursing unit and the patients themselves. The membership would include assistant directors, supervisors, head nurses, staff nurses, practical nurses, nursing assistants and/or hospital aides. Here again, representatives from other departments may be invited to participate as related problems arise, such as medical, dietary, social service, psychology.

Another important committee in a well organized nursing service is a Staff Development Committee, in which the leadership comes from the Director of Nursing Education. Here again the membership is representative of all organizational levels, giving them a part in planning for in-service needs for their specific levels. This is an example of the principle that when personnel have a part in problem solving and policy making, they will be more willing to carry out plans.

We strongly believe that while nursing service and nursing education may be separate departments, they should operate under the leadership of the Director of Nursing. In this way the programs in nursing education are geared to meet the needs of nursing service personnel so that they may in turn meet the needs of patients(3).

PEOPLE CENTERED SUPERVISION

An essential adjunct to management of nursing service is an organized program of supervision. It sets lines of authority, points ways to delegation of authority and gives everyone a specific place in the organization with each employee having one immediate supervisor. An organization chart is essential. Because changes take place and accumulate, periodic re-examination of a department's operations are important. The organizational chart can also be helpful to

nursing service personnel to discover how their efforts are related to the work of persons in other departments. The nursing staff needs to develop a comprehensive perception of the hospital's operation(3).

The organizational plan is also the key that opens the way to the delegation of authority all down the line to the immediate supervisor of each employee. Here we learn to whom and for whom we are responsible. As we move more and more toward decentralization of authority, we must select people carefully for designated positions and permit them to carry out their functions with little interference within a control system. This points to the importance of the selection of the right person for the right place. Here administrative skill becomes an art in which we meet the nurses' needs, and motivate the nurses to meet patient needs. Placement of a nurse in a specific job for which she is suited and helping her grow is an important device in stabilization and retention of nurses for psychiatric hospitals.

COMMUNICATION

Effective communication involves more than words; machinery must be set up for getting communications up, down and across. This includes keeping informal, as well as formal, channels open and functioning. There is a need to build adequate follow-up machinery, to shepherd information through to the final step. The feed-back received from communication determines the effectiveness of the communication efforts. Some of the factors in an organization affecting communication are: first, the choice of media, such as, word of mouth, bulletins, house organs, memoranda; second, timing; and, third, the relationship between the sender and receiver in terms of status, position, *etc.*(1, 2, 3, 6).

The greatest factor in communication, however, is the human element. An understanding of the basic process of interaction between individuals is essential for effective communication.

People come from different backgrounds with different value systems and beliefs. The individual behaves in various ways depending on how he feels about his place in the organization. If he has had a voice in

making decisions, he accepts information and orders more readily.

THE PLACE OF THE PROFESSIONAL NURSE

The professional nurse is responsible for the nursing care of patients. This is unalterable, fundamental and permits no exceptions. This is required by the Joint Commission on Accreditation of Hospitals, by the American Psychiatric Association and by the Veterans Administration (8, 11, 12). Since the professional nurses constitute only a small percentage of total nursing service personnel, most of the day-to-day care is rendered by practical nurses, technicians, aides, nursing assistants and attendants. Because of the greater depth and scope of her education the nurse is prepared to accept the responsibility of total care. Every professional nurse in the mental hospital must function as a supervisor no matter what her rank or title. There is no one else in the whole psychiatric setting who is in such a position for co-ordinating all the efforts of various disciplines to meet the needs of the patient.

It is more important today than ever before for the nurse to be able to carry on intelligent and successful liaison between the patients and the various disciplines who have responsibility in their care. It is the professional nurse, the leader of the nursing team, who more than any other person creates the atmosphere of patient care. Through her leadership the patient is respected as a person with individual needs; she realizes the importance of maintaining the dignity of the patient. She also understands the psychological importance of the physical environment to the patient.

Recently there is a changing attitude toward all the activities that rightly should be thought of as belonging to the professional nurse. She is an administrator, teacher, counselor, supervisor, and therapist. The responsibilities of the professional nurse are both administrative and educational in nature, regardless of whether she is a supervisor, head nurse or staff nurse.

Since it is impossible for the professional nurse to carry personally the entire administrative and teaching load in nursing service, the delegation of duties and responsibilities to others becomes most im-

portant. Responsibility for supervision is involved in all the professional nurse's many duties; the greatest of these is the supervision of the non-professional worker. Plans may be carefully made with allied services for the patient, orders well written, clear and up-to-date, duties delegated, and still nursing care has the tinge of custodial care. Good nursing is therefore dependent upon the professional nurse knowing her patients, the care they are receiving and its results.

IN-SERVICE EDUCATION

The nurse administrator's greatest asset for improved nursing care is a dynamic and democratic in-service program. In-service education stimulates the growth of the nurse after she is on the job. The nurse has needs which are not met on a pre-service level as a student, or she has needs that are different from other hospitals in which she has worked, even as a psychiatric nurse. Perhaps the curriculum in her school was "What, When and How to Do," instead of being based on broad, general principles and preparation that enables her to function as a professional nurse in whatever nursing situation she may find herself (3, 11, 12).

The dynamic professional nurse will survey the area she is responsible for and will seek guidance from her supervisor and personnel in the nursing education department as to possible ways and means to improve nursing care. Usually this is accomplished in the following order: through nursing care plans, nursing care conferences and nursing care assignments.

In a nursing care plan, the doctor, nurse and ward personnel identify the philosophy, objectives and goals that may be realistically met for the patients for whom they are responsible. For example, the philosophy, objectives and goals for a geriatric ward would have a different emphasis from those of the acute and intensive treatment area.

The nursing care conference does more than anything else in changing attitudes and feelings toward patients that have been in the hospital for many years. Emphasis is placed on present needs and behavior, not on what the patient was like ten years ago. This group planning for nursing goals for patients is the most effective way of getting ideas from the total group.

When the two preceding phases have been established with a positive approach the assignments in patient care become meaningful and purposeful and they are accepted with interest and enthusiasm. When these three steps are implemented you find counseling, evaluations and ward administration improving far beyond your expectations, as your whole program is people-centered.

SUMMARY

The present day concept in nursing service administration is to demonstrate administrative functions that will provide therapeutic and satisfying situations for patients and personnel. Administration is the management or guidance of an organization for the most effective accomplishment of its stated goal.

The goal of a nursing service organization is more specifically to give continuous care to the patients; to recognize the physical, emotional and social needs of the patients; to meet these needs insofar as possible; to assist in restoring the patients to their optimum health status. In working toward this goal, nursing must maintain itself internally by recognizing the needs of the individuals who make up a nursing service; it must adapt itself to its environment, and working harmoniously with other services of the parent organization (9).

Only through democratic administration can therapeutic and satisfying situations be created for both patients and personnel. Such administration recognizes the worth of each individual. When employees have a part in planning and when they feel respected and accepted, they derive more satisfaction from their work and are better able to respect and accept their patients and co-workers.

Skillful delegation of administrative duties at all levels in nursing service is important if the professional nurse is to be utilized effectively in improving the quality of nursing care in our psychiatric hospital.

This paper has attempted to emphasize the concept of good management principles, in administering nursing services. If we are to accomplish our patient-centered goals, our administration must be people-centered.

DISCUSSION

WILLIAM S. HALL, M.D. (Columbia, S. C.).—Until recent years, relatively little study and research have been devoted to the science of organizations and administration. It is gratifying to observe that this picture is rapidly changing. The School of Business Administration at Harvard University, The School of Public Health and Administrative Medicine at Columbia University and The Center for Programs in Government Administration at The University of Chicago are only a few of the

fountainheads that are now busily engaged in exploring this new science.

I would like to comment on the following quotation from the paper under discussion :

Leadership need not be authoritarian. A leader can assist in defining goals without categorically imposing them ; he can discuss alternative methods of proceedings without ordering them ; he can encourage spontaneity and individual difference without fostering anarchy ; he can give support and approval without creating dependency. It is a role requiring a delicacy and an awareness of the social consequences of action but it is not an impossible role to play.

The speaker is in agreement that this is the ideal to strive toward ; however, in most large mental hospitals of long standing, it is very difficult, if not almost impossible, to convert such institutions from custodial to active treatment centers unless authoritarian methods are utilized when necessary. This is so because, inasmuch as these institutions are staffed with what might be termed a hard corps of faithful employees who rendered diligent and faithful service during the custodial era, they frequently resist changes and innovations that are conducive toward the "treatment team" approach. In such cases, after the more genteel and democratic methods have failed it is necessary that *staff* administrative officials command and enforce obedience and, even then, several years are usually required to accomplish the desired objective.

It should be remembered that there is a strong tendency for so-called *Line Personnel* to become "non-therapeutically oriented." These people become so involved in the sub-goals of the organization, such as, ward census figures, laundry count, supply requisitions, and housekeeping, that primary treatment goals are often relegated to "some other time" and, of course, in the usual busy ward this deferred period seldom, if ever, transpires.

As you know, the *Line Personnel* actually operate the ward and it is very important that the so-called administrative or *Staff Personnel* recognize the aforementioned tendency because, as the authors of the paper under discussion state :

It is the professional nurse, the leader of the nurse team, who, more than any other person, creates the atmosphere of patient care.

Of interest in this connection are the research findings of Malcolm G. Cynther and Boris Gertz of the South Carolina State Hospital. Edwards Personal Preference Schedule scores were obtained by these researchers from 220 student nurses who were representative of South Carolina's student nurses. Raters independently selected the best and worst nurses in terms of technical competence, dependability, initiative, attitude toward patients and colleagues as well as related factors. The authors of this research work state :

Our results which suggest that student nurses are more concerned with orderliness and sticking to a job until it is finished and less interested in leadership and autonomy than their peers neither confirm nor disconfirm earlier work, as these variables have not been previously investigated. However, these results, in conjunction with the nursing students' tendency to feel more timid and inferior than other women their age, indicate that at least one motive for these girls entering the nursing profession is an attempt to find a stable, well-structured situation in which they will be told what to do and in which they will not be expected to show initiative or extroversive qualities.

The special concern with orderliness, neatness, and careful planning of the "poor" nurses suggests that such nurses would feel particularly comfortable in custodially-oriented hospitals in which security and neatness of wards are considered more important than socialization with patients.

This research work, if confirmed by other investigations, would suggest that nursing administration will have to devote more attention toward overcoming these natural tendencies and personality characteristics of nursing personnel. This is especially true if leadership capabilities on the ward level are to be enhanced.

It is also well that the nursing administrator keep in mind that the patient often views *Line Personnel* as "adversaries" because nursing employees on the ward level are recognized as the prime movers in

bringing about restrictions of patient privileges. The nursing administrator should promulgate measures to lessen these interpersonal feelings in every possible way.

Administration officials would do well to take cognizance of the fact that the professional nurse, as well as the non-professional nursing employees, are frequently guided by and utilize to the fullest, an ambiguous form of cerebration known as "common-sense thinking." Although this nomen is anything but scientific, this form of rationalization is so universal that we need to know more about it. Much research is necessary here, as well as in the whole realm of administration and management of people.

"Administration" has been described as a

continual cycle of planning, organizing, marshalling of resources and controllership, with emphasis on the word "continual." The nurse administrator should be judged in terms of the distance she progresses from "status quo" forward and up the rungs of the ladder to higher accomplishment.

Slightly paraphrasing a statement made by the authors of this excellent paper, from personal experience your discussant would say that, to properly and effectively restructure the administrative organization of a mental hospital from the traditional to the creative and permissive type requires a very long time, confirmed and unshaken confidence, together with ultra and extreme tolerance.

COMMUNITY PRESSURES AND A STATE HOSPITAL PROGRAM FOR CHILDREN¹

JOSEPH J. REIDY, M.D.²

Public mental hospital care for children has been inadequate. All of the reasons which account for poor quality of care of adults in some state hospitals apply as well to the care of children. In addition, it appears that the citizens, the public officials and even many professionals in the fields of psychiatry and of child welfare are less aware of the treatment needs of children than they are of adults. Because of this twofold lack of facilities and of knowledge, the state hospital system is likely to encounter many obstacles when it attempts to provide inpatient psychiatric services for children. This paper draws upon the experience of a recently opened facility in Maryland, the Esther Loring Richards Children's Center, in providing short-term, intensive treatment for seriously disturbed pre-adolescents. It is an account of our experiences and success in providing care of a high quality, and of some of our difficulties.

Institutional psychiatric treatment for children as distinguished from institutional care of children in orphanages, training schools and similar places is relatively new, and almost all the institutions which do give effective treatment have been administered by private agencies. Institutions like The Bradley Hospital in Providence and the Southard School in Topeka, which opened in the 1930's, have had small populations of 20 to 60 patients, and large staffs with a ratio of one or two adults to each child, and have been very expensive. The cost today of treating a child at one of these centers ranges from \$20.00 to \$30.00 a day.

A child who is not admitted to a private institution cannot receive adequate treatment in most states. In 1956 the Department of Public Welfare of Illinois, through the efforts of Dr. Raymond Robertson, pub-

lished the "Report of Survey of State and Territorial Facilities and Programs for Mentally Ill and Emotionally Disturbed Children"(5). This report stated that almost three-fourths of the states were housing and treating children with the adult population of their state mental hospitals. Only 4 states had psychiatric wards for children. Although the Illinois survey stated that children constituted approximately 1% of the resident hospital population, it added that "the information at hand does not clearly indicate the number of children under care." Although 10 states had made or were making surveys to estimate the total number of children needing public institutional care, the Illinois survey commented that "apparently little attention had been given to estimating the over-all need." The conference in 1956 of the American Psychiatric Association and the American Academy of Child Psychiatry on inpatient psychiatric treatment for children also reported that there were few public programs and there were no accurate and reliable studies of the needs for inpatient care for children(6). The publications of the 1960 White House Conference on Children and Youth point out the same needs(8).

PLANNING THE CENTER

In 1956 Maryland also had no separate facilities for children in its public hospital system, although it had experimented briefly with a ward for 9 children in one of the state hospitals. In 1952 a study was published by the Baltimore Council of Social Agencies identifying 131 children in Maryland who needed "closed" institutional care(1). This survey provided a basis for community and legislative action which resulted in the opening of the Esther Loring Richards Children's Center in September 1958.

A few months before the opening of this Center, I came to Maryland as Director of Child Psychiatry of the Department of Mental Hygiene and as director of the new

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Esther Loring Richards Children's Center, Owings Mills, Md.

center. It turned out that there were advantages in one person having this double responsibility. The problems of beginning a particular treatment program and of formulating a state-wide policy were closely related. The success in treating children admitted to the Center was to depend in part upon what was done regarding the children who were not admitted. Almost every individual problem relating to location, construction, budget, staffing, relationship with the community, treatment of the family, the "open" hospital setting has this double aspect.

I will mention here briefly a few problems which are extensively discussed elsewhere(6). There were, in my opinion, serious faults in the physical plant of the Ester Loring Richards Children's Center. The planning for the physical aspects of such institutions is not a simple matter and must include careful consideration of size, functional design, construction materials, relationship to population centers, to transportation, to other hospitals, universities and medical schools. The director should be selected early enough to allow him to participate in the planning and he should have the right to choose his staff.

In choosing staff as well as in submitting the operating budget there should be no compromise on quality of treatment. This applies, of course, to treatment for persons of any age, but it is often difficult to show departmental officials why so many people and so much money is needed to take care of *children*. My search for qualified persons at times involved refusal to accept job specifications and insistence that positions be given higher classifications. It appeared that classification officers were accustomed to consider the worth of an individual in terms of the number of persons for whom he has nominal responsibility, rather than in terms of the quality of treatment he gives to those in his care. It appeared that some officials felt that a public program could be less expensive than a private program. These persons had to understand that because trained professionals are few it is necessary to pay adequate salaries to keep them in state programs, and because these children need individual care large staffs are necessary.

ADMISSION POLICY

A decisive factor in any program is the admission policy. Some children can be helped in a few months, others will require years of care. There are children who are best treated in an open setting where they can have a relative freedom to move in and out of the community, a setting in which they can test their impulses against authority of adults, their relations to peers and the many other factors which comprise "reality." Other children, fewer in number, need the protection and restraint of a closed setting. Age is a factor, and so there must be separate programs for the pre-school, pre-adolescent, and adolescent. Some children will need emergency care, or observation for the purpose of diagnosis. Children who have severe physical illnesses or handicaps will need the services of a general hospital. How can all of these children be cared for?

One approach is to admit to one program all children who cannot be cared for in the community. This serves only to remove temporarily some burdens from the community. Depending on the design of a given facility, treatment programs may be instituted for two or three types of children, but not for all of them. Another approach is to build all the units simultaneously, so that each unit may receive only those patients it is equipped to treat. This would provide good treatment but it might be difficult to persuade taxpayers and legislators to build simultaneously all the units needed in a comprehensive program. Another solution is to provide for all of these units in one large children's hospital, and a few states are now planning such programs. Perhaps because of my experience in small treatment institutions I view with alarm the construction of children's hospitals of two, three or four hundred beds. If treatment of these children is a team approach, depending heavily on milieu therapy and psychotherapy and very sparing in the use of physical methods of treatment, then there is only a limited number of children that each team can handle. I have often been asked what is the optimum number of children in any active treatment program. I can only answer that the director and each member of his treatment staff should know

intimately each child. If an institution is quite large, say 200 children, it must be divided into a number of smaller, distinct treatment units. I feel large hospitals for children will not be adequately staffed, that the children will not receive the close personal care they require.

If a state begins with one program, the community must know that this program cannot treat all children. Some states have called their first treatment units "pilot programs." Some states anticipated the pressures to admit children and have provided in their laws that the control of admissions rests with the superintendent. In Maryland the commitment laws were not changed; children can be sent to the institution by court order or by the certificates of two physicians. Except for age limit no criteria for admission were formulated when the community was asked to give its support to obtaining this facility. Before the institution opened the persons in the state hospitals were not clear about what type of program was being provided and each person in the community saw the center as able to care for any child who could not remain in the community. A large number of children had been referred to the center. Some were in the adult mental hospitals, some in correctional institutions, others in their own homes or foster homes. They ranged from relatively mildly disturbed children to those with chronic, severe personality disorders. It was clear from inspection of the referral material that these children could not be treated in one program and it was also clear that several programs could not be carried on in the single building which would constitute the entire physical plant of the Center.

With the help of professionals in the state hospital system and in the community, an admission policy was prepared and approved by the Commissioner of Mental Hygiene. This policy defined the program as serving children under 14 who could be treated in a relatively short period of time in an open setting. It required an examination of the child and interviews of his parents before admission and that the community agency remain active throughout the child's stay in the Center.

The staff has little legal authority to con-

trol admissions and there was opposition regarding the examination and evaluation of referred children. Some courts, physicians, and community agencies were accustomed to send patients to the state hospitals without prior consultation with the hospitals, even though all of these hospitals had "pre-admission" clinics. In these circumstances the new Center would have quickly become a custodial institution.

To this date the staff at the Center has not been forced to admit any child whom, in its judgment, it could not help. This success required considerable effort. The staff visited many clinics, courts and community agencies. We explained the program to those persons dealing with mentally ill children, and attempted to convince them that in the long run no one would be helped if all problem children were admitted to the Center. When an emergency arose, usually because a judge was insistent that a child be sent to the Center, I went immediately to the judge to discuss the problem. When we could not admit the child, and it appeared that he should be removed from the community, as Director of Child Psychiatry for the Department, I directed that the child be sent to one of the adult hospitals. I visit those hospitals regularly, examine every child admitted and help the staffs to plan for them. Some of the children should not be on wards with the adult patients and while such a resolution of the crises has safeguarded the work of the Center it is neither good for the particular child nor popular with the community agencies or the state hospital staffs. But again the role of Director of Child Psychiatry is an asset, because I represent the Department on all the state-wide committees dealing with disturbed children. I have been able to tell these committees of the limitations of the programs at the Center and at the state hospitals, and indicate the need for other programs. One result was that the Council of Social Agencies began a re-study of the needs of disturbed children. Recently the staffs of the training schools for delinquents have met with representatives of the mental hospitals to plan for the treatment needs of adolescents.

Many persons who initially criticized the Center for its "rigidity" now understand the

necessity for the staff to adhere to its admission policies. If this was to be a short-term, open type of treatment Center it was necessary that it admit only the children who would benefit from this treatment, and the staff could decide only by examining those referred. When the judges and professionals became aware that the Director of the Center had responsibilities for planning for *all* children who needed hospital care, and that the Department of Mental Hygiene was also trying to help those who could not be admitted to the Center, they were more cooperative.

The question is often asked: "Why did you start with a short term, open program for pre-adolescents?" Our answer has been that the turn-over of patients would be greater if we concentrated on those needing short term care (less than a year). In the pre-adolescent group there were few children who needed "closed" care. Parenthetically, it appears that it is seldom necessary to hospitalize a child for observation and diagnosis if the outpatient evaluation is thorough. We require accurate and complete referral reports and our examination includes psychiatric and psychological examination of the child, one or more social service interviews with the parents, conferences with the referring agency, and often psychiatric and psychological examination of the parents. In only one instance did the staff feel that it was necessary to admit a child for observation, and two days of observation were sufficient. It is difficult to treat children in a relatively small program if there are in the hospital children who have not been diagnosed and whose treatment needs are not known.

The majority of cases are presented as emergencies, and in the beginning "emergencies" had to wait as long as 8 or 9 months to be examined. The staff advised agencies that if a child could not remain in the community until our evaluation, he could be sent to the adult hospital. If we subtract the children who were transferred to the hospitals from the correctional schools, surprisingly few pre-adolescents were sent to the adult hospitals. The staffs of these hospitals felt that few of the children committed to them were indeed emergencies. To my knowledge there has been

little written on what constitutes a psychiatric emergency in pre-adolescent children. The dangers of suicide and homicide, the main reason for emergency hospitalization of adults, are, according to the literature, rarely present in pre-adolescents. For many of these children the community had exhausted all its resources and the emergency was a placement problem rather than a safety measure. Some children with severe personality disorders make suicidal threats or gestures in order to control adults. Perhaps the findings of Goldberg and Robinson regarding the handling of psychiatric emergencies in a psychiatric clinic are applicable here(3). These authors studied 82 cases that were given immediate service because they were judged emergencies. They found that "all but 2 were not psychiatric emergencies and could have been handled in a routine fashion had clinic personnel adequately assessed family history and more fully explored the symptomatic picture."

FAMILY-ORIENTED TREATMENT

A basic part of the treatment at the Center is treatment of the family as well as the child. Persons in child guidance practice as well as in inpatient work affirm that the illness in the child bears some relationship to the illness or maladjustment in other members of the family. If a child is to become well and remain well, his parents must receive help either in changing certain of their own patterns of living or in dealing with the child. Our family-oriented program is described in detail in another paper (4), but I wish to stress certain aspects of this program. If the child is to return to his family he should not be entirely separated from it while at the Center. The parents care for the child at home on weekends, and this provides them and their child with opportunities to build better family relationships with the help of the Center and the community agency. The child does not feel totally rejected and abandoned by his parents, the parents do not forget about the child or his problems. They do not feel totally guilty about their failure or completely inadequate as parents because they are thus given an opportunity to act as parents and to take responsibility for the im-

provement in their child. Some persons considered this procedure an unjustified departure from state hospital practice, and that it was adopted because of weekend staff shortage. These children were thought to be "too dangerous" to be allowed so much freedom. Such objections do not apply to a group of children selected because they can be treated in an open hospital setting.

Parents have been enthusiastic about this program even though they often have to travel long distances each weekend. They accept responsibility and have been eager to make the child's weekends pleasant. The child is not required to make a total adjustment to an institutional way of life and when he is discharged he does not have to make a completely new adjustment to life outside of the institution. The weekends provide material for the Center's staff to use in treatment of the child and material for the community agency to use in treatment of the parents.

THE CENTER AND THE COMMUNITY

Because the state hospitals have been isolated from the community, the agencies referring patients to these hospitals have lost contact with their patients and have had to leave the total responsibility for treatment to the hospital. The hospital staff labors under great handicaps in providing a comprehensive treatment program which goes beyond the individual patient and reaches into the family and community. The Esther Loring Richards Children's Center works in partnership with the community in the treatment of the child and his family, and discourages agencies from terminating their services when a child is admitted. The Center exists to provide necessary hospital care, and to effect enough improvement to enable the child to return to the community. He and his family may still need help and it is not practicable for the Center to attempt to provide services which should be available in the community. Bloch and Behrens, in their study of referrals for residential treatment in New York State, highlighted the absence of continuing responsibility for the care of these mentally ill children (2). It is the community, through its agencies and clinics, which should provide this continuity of care and responsi-

bility, using the inpatient treatment center as a specialized resource in their total plan.

Because of the inadequacy of treatment facilities in many communities, there are pressures on the Center to accept children who could be helped in the community by psychiatric clinics, family agencies, specialized school programs, foster care plans. When the staff of the Center, as a result of its examination has seen the need for treatment of the child in the community rather than removal of the child from the community, it has so recommended and declined to accept the child. In these same communities the Center has difficulty in finding agencies willing to assume the responsibility for working out a treatment plan for the admitted child, for offering casework services to parents, for help in discharge planning and for followup after discharge. It would appear that the community which has the most highly developed facilities for non-institutional treatment of children will refer to the inpatient center only those children for whom inpatient care is the treatment of choice, and will, by their skillful cooperation with the center, render the treatment more effective. This was stated a good many years ago by Carl Rogers (7), and has held true in our experience. It is from those communities which lack adequate local services that we have received the greatest pressure to accept children who were not in need of institutional care. If all communities had reasonably adequate local services for neglected, dependent, delinquent and mentally ill children, we might be able more easily to arrive at a valid estimate of the need for inpatient services. The danger, I believe, in estimating bed needs without taking into account the need for community services, is that we may provide too many beds and facilitate the community unloading its due share of responsibility on the state hospital system. Since we have not at this date an over supply of beds perhaps we can build wisely.

CONCLUSION

I have tried to show how a public hospital can give the high quality of care given by private residential centers. Except for our plan of having the child live with

his family each weekend, there are no new concepts of care but rather an application of those principles of modern psychiatric care which are well known and which have been practiced for years by well known hospitals and social agencies. There must be a determination to resist pressure from many sources and a willingness to work with community agencies. If such a program can surmount the initial difficulties it can demonstrate by its treatment results the effectiveness of its work.

THE "ADEQUATE RELAXATION INTERIM" FOLLOWING SUCCINYLCHOLINE ADMINISTRATION IN ELECTROSHOCKTHERAPY

CHARLES BUCKMAN, M.D., ARTHUR KRELL, M.D., IRVING PINSLEY, M.D.,
ARTHUR S. IMPASTATO, M.D., AND DAVID J. IMPASTATO, M.D.¹

Succinylcholine chloride (SCC) is used in the convulsive therapies for the purpose of eliminating bone and muscle injuries. However, the optimal time for the administration of electric current following the intravenous injection of SCC is still controversial. EST has been administered from 10 to 65 plus seconds following the injection of SCC. As each worker attempts to give the grand mal at the time of maximal muscle relaxation, the marked variation in the time of giving such stimulation is due to a difference of opinion as to when this occurs. Murray(1), Holmberg and Thesleff(2), Impastato and Berg(3), Glover and Rosium(4) apply the GM stimulus from 10-20 seconds after the SCC injection, while Moss, *et al*(5), McDowell, *et al*(6), Price and Rogers(7), Richards and Youngman(8) and Alexander, *et al*(9), stimulate from 45 to 65 plus seconds after the SCC injection.

The purpose of this study is to determine the optimal time or interim following the injection of SCC when the grand mal may be given.

MATERIAL

Twenty patients for whom EST was prescribed were selected at random: 11 females, age range 19 to 60 and 9 males, age range 23 to 61. Among these were 16 schizophrenics: 8 catatonic, 4 paranoid, 2 hebephrenic and 2 mixed types. Of the rest, 2 were involuntal; 1 paranoid and 1 melancholic; 1 manic-depressive depressed and 1 psychotic due to alcohol. Physical conditions of all patients were grossly normal and none was a poor risk.

EST was administered 3 times weekly and at each treatment recordings were made of: 1. The interim of time between the injection of SCC and the appearance of the circumoral fasciculation caused by

the SCC; 2. The interim between the appearance of the circumoral fasciculation and the administration of the grand mal stimulation; 3. The degree of muscle relaxation. The grand mal was given at various interims, each observation being recorded on consecutive treatment days. At the first treatment the grand mal was applied 5 seconds after the circumoral fasciculations were first seen and on subsequent treatments the interim was lengthened (see Fig. 1). In all patients atropine 1/75 gr. was administered I.M. ½ hour before each treatment. A standard dose of 15 mg. of SCC was used in all patients. No oxygen was used either before or after each treatment. No barbiturates were used.

SCC CIRCULATION TIME

After one works with SCC, even for a short time, it becomes obvious that the interim between the injection of SCC and the appearance of perioral fasciculations depends upon the circulation time. We recorded the circulation time of the SCC in all patients and found it constant for each of them. It varied from one patient to another, the average being 13 ± 5 seconds.

In all of these patients we also measured the arm to tongue circulation time with calcium gluconate and found it to be 1 to 2 seconds less than the SCC circulation time. We mention this to point out the variability of the interim between the injection of the SCC and the appearance of perioral fasciculations and to urge that time measurements of the effect of SCC be made not from the beginning of the SCC injection but rather from the appearance of the perioral tremors. This, we believe, is a fixed invariable point and determinations of interim periods starting from this point will yield more accurate results. We have done this in our work.

¹ From Kings Park State Hospital, N. Y.

GRAND MAL STIMULATION AT VARYING INTERIMS FOLLOWING SCC PERIORAL FASCICULATIONS IN STANDARD AND PM-GM EST TECHNICS

PM-GM TECHNIC

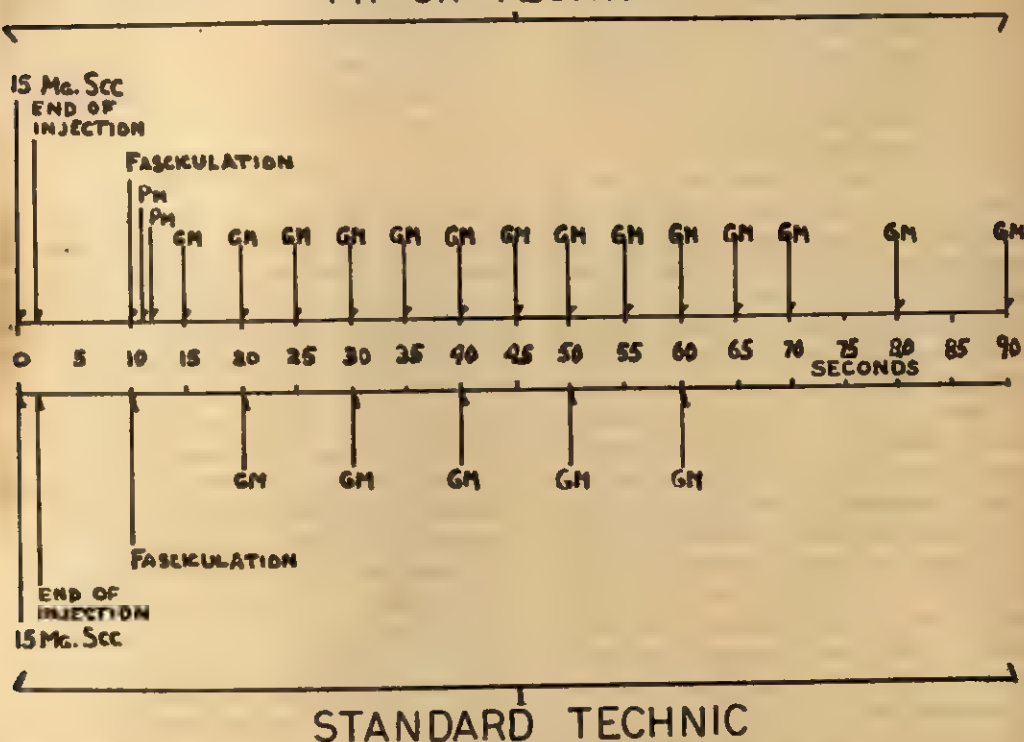

FIGURE 1

METHODS OF EST APPLICATION

Standard Technic: SCC was injected within 2-3 seconds and at 10-20-30-40 and 50 seconds following the appearance of the perioral fasciculations the grand mal was given with the Molac II Alternating Current Machine in the "High" position (10). (For the purpose of our study the Molac II can be equated to any ordinary AC machine.)

PM-GM Technic: SCC in many patients causes unpleasant feelings of suffocation if the grand mal is not given soon enough. This undesirable effect occurs within a few seconds after the appearance of perioral tremors. To circumvent this the patient is either anesthetized with a barbiturate prior to the injection of the SCC or rendered unconscious with a petit mal stimulation at

the first sign of perioral fasciculations. This latter method is known as the PM-GM Technic(11), described as follows: a small dose of SCC is quickly injected intravenously. As soon as the perioral tremors are seen two petit mal stimuli are given in quick succession and followed 5 to 10 seconds later by the grand mal.

For our experiment we modified this technic as follows: SCC was injected within 2 to 3 seconds and as soon as perioral twitchings were seen 2 petit mals in quick succession were given with the Molac II machine in "Low" position (with the classic AC machines the petit mals may be given by setting the machine at 110 volts at 0.1 seconds). Then, on successive treatments the grand mal was given with the Molac set in the "High" position after 5-10-15-20-25-30-35-40-45-50-55-60-65-70-80-

90 seconds. The degree of muscle relaxation in both methods was rated as follows :

0 = No relaxation

1 plus = Forearms flexed on arms, considerable force required to unbend the forearms.

2 plus = Forearms flexed on arms, little force required to unbend the forearms.

3 plus = Forearms not flexed. A very soft convulsion present.

4 plus = Convulsion barely noticeable.

The interim between the first appearance of the perioral fasciculation and the GM stimulation we have named the "waiting period." In the Standard Technic, after a waiting period of 10 seconds, the degree of relaxation was 1 plus. Following a waiting period of 10 to 20 seconds relaxations were 2 plus. The waiting period between 20 to 30 seconds induced further relaxation in most patients to 3 plus. In some patients, ratings of 4 plus were obtained. The degree of muscular relaxation observed after the waiting period of 30 to 40 seconds varied in no way from that of the 20 to 30 seconds waiting period. Beyond the 40 second waiting period the degree of muscular relaxation diminished and after 50 seconds ratings were reduced to 1 plus.

With the PM-GM Technic, after a waiting period of 5 seconds (since the PM are given as soon as the perioral fasciculations

are seen, for practical purposes the two may be said to take place at the same time) the degree of relaxation was already sufficient to be rated as 1 to 2 plus. In most cases, after 10 seconds the muscle relaxation was 3 plus and in some cases 4 plus. This degree of relaxation was noted to extent to 70 seconds following petit mal application and only diminished in intensity after that period of time.

CONCLUSIONS AND SUMMARY

The foregoing investigation demonstrates that the SCC injection causes relaxation lasting for a variable time depending upon the EST technic used. With the classic AC treatment the interim begins 20 seconds following the appearance of perioral fasciculations and lasts for 20 seconds. With the PM-GM technic the interim begins in 10 seconds and lasts 70 seconds.

After 40 seconds with the Standard Technic and 70 seconds with the PM-GM Technic, the degree of relaxation lessened and treatments given at this time or later are potentially capable of producing injury. It may therefore be concluded that with the Standard Technic, without using barbiturates and quickly injecting 15 mg. of SCC, one should not wait longer than 40 seconds after the onset of perioral fasciculations. To administer the grand mal with the PM-GM Technic it is apparently

RELAXATION RESPONSES WITH GM APPLIED AT VARIOUS INTERVALS FOLLOWING SCC PERIORAL FASCICULATION IN STANDARD AND PM-GM TECHNIQS

FIGURE 2

safe to wait up to 70 seconds. We were surprised to discover that the double petit mal greatly prolonged the "adequate relaxation interim." A possible explanation for this might be that the petit mal application releases acetylcholine which re-enforces and prolongs the action of SCC. Further study to discover the actual reason why the petit mal re-enforces and prolongs the action of SCC, should be undertaken.

THE CULTIVATION OF COMMUNITY MENTAL HYGIENE LEADERSHIP ABILITY AS A PART OF A PSYCHIATRIC RESIDENT'S TRAINING¹

HOWARD M. KERN, JR., M.D.,² AND CAROLINE A. CHANDLER, M.D.³

Changing attitudes towards mental health and patterns of care for the psychiatrically ill have greatly increased demands for psychiatrists experienced in community mental health and motivated to work in this psychiatric specialty. In the State of Maryland we are developing a program of training in public health psychiatry for psychiatric residents which we believe is unique in the United States. The purposes are: first, to incorporate the practical and theoretical aspects of public health psychiatry into the psychiatric residency programs in the State of Maryland; and secondly, to provide psychiatric service of a high quality on a consistent basis to understaffed areas. The program is a cooperative venture of the State Health Department and the various university, private, and state psychiatric training centers in Maryland. We believe that it is a pattern that can be readily adapted to other areas, using existing personnel and adding little to the cost of present mental hygiene programs.

The training is based upon the point of view that leadership, inventiveness and industriousness are best furthered in the maturing physician by placing him in a position of responsibility and providing him with a source of senior advice without continual, on-the-spot supervision.

Practical experience in community mental health has not been included heretofore in the usual resident's training, even though he may have considerable experience in a large university or community clinic. These firmly established and well operated departments insulate the resident from the community by their size, and by the division of responsibility.

In our present enterprise, designed to improve the residents' understanding of community psychiatry, senior psychiatric residents serve as consultants in mental health to the county health departments within commuting distance of the training center. Each resident has the following responsibilities:

1. Serving as psychiatric consultant to the local health department and staff, to private physicians and to other community agency workers.

2. Assisting the county officer in planning a mental health program.

3. Acting as director of a part-time mental health clinic in the county department and assuming the medical responsibility for providing psychiatric diagnosis and treatment for adults and children.

4. Supervising the work of non-medical clinic staff and handling correspondence and reports in connection with the program as required.

5. Participating in the in-service education of health department staff and other professional and public mental health educational programs upon request of the local health officer.

The counties selected for this educational enterprise have been small enough and distant enough from the metropolitan area, that each is a fairly self-reliant community, with a structure and leadership pattern which can become familiar and understandable within a moderately brief period. The compactness of the counties permits the resident to get an overall view of the interaction of various agencies. In many instances, there are certain key individuals in the community agencies who can be dealt with informally and by personal contact. In addition, there are fewer buffers between the psychiatric consultant and the community agencies and leaders than exist in the large metropolitan clinics. The psychiatric resident is very much on his own in a situation demanding forbearance, tact,

¹ Presented at the Pan-American Medical Association meeting in Mexico City, May 5, 1960.

³ Chief, Office of Mental Health and Child Health, Maryland State Department of Health.

flexibility and the willingness to learn. He is challenged by a job requiring ingenious solutions to immediate problems and by stimuli arising from the opportunity for leadership.

Participation in the program is based upon the recommendation of the resident's chief of service, and approval of the Chief of the Division of Mental Health for the State Department of Health, and the local health officer. The participants must have had at least two years clinical psychiatric experience and must have indicated by their past performance that they have potential for leadership and a flexible orientation towards the field of psychiatry. Each resident spends one work day per week as consultant to the local health officer of a rural county, and in this position he is psychiatric director of the mental health clinic for that county. While on the job he has no direct senior psychiatric supervision. This is provided in the form of individual conferences with the Supervisor of the Training Program and the Chief of the Division of Mental Health of the State Health Department. Group meetings and discussions are led by consultants to the State Department of Health in the specialties of psychiatry, psychology, psychiatric social work, and psychiatric nursing. Academic experience in problems of public health psychiatry are provided by a seminar in community mental health given in the School of Hygiene and Public Health of the Johns Hopkins University. By periodic presentation of his community experience to the staff of his parent institution, the resident evaluates his experience and receives the support and criticism of fellow professionals not directly concerned with the state program. The

resident compensates his parent institution for the time away by working additional time during evenings and weekends and is, in turn, compensated by the training experience and by a stipend from the health department. In total, they spend 4 work days, plus 11 hours in supervisory and seminar sessions per month.

To illustrate the variety of experience present in the program, the following figures are offered covering the 5-month period of one resident's experience. During that period he saw 30 new patients for evaluation and had a total of 65 followup patient visits. There were also 55 interviews with relatives, referring agencies and local physicians. He attended 5 meetings with the local mental health association representatives, 4 with school authorities, and made one public presentation to the local mental health association. He had direct personal contact with 28 key community personnel including physicians, public health nurses, welfare workers, school superintendents, school principals and counselors, clergymen, and representatives of law enforcement, court and probation services.

In summary, we believe that the Maryland program enriches the resident's training experience, expands psychiatric residency programs, and provides mental health services to areas that have always been difficult to staff. Although this program is in the early stages of development, there is some indication that it will encourage many psychiatrists to view problems of community mental health sympathetically and consider public health psychiatry as a possible area of specialization.

A LONGITUDINAL STUDY OF SCHIZOPHRENIA¹

AND T. T. COULTER, Ph.D.²

The study was designed to document the long-term clinical course of schizophrenia, as reflected in the present status and past history of a group of World War II veterans diagnosed as schizophrenic, and under surveillance by the Vancouver office of D.V.A., since the end, or shortly after the end of the War. The first objective of the study was to determine the relationship between the present status of the patients, and the onset and course of the disease. The next two objectives were concerned with ascertaining the effects of direct social support, that is, by the patients' families, and indirect social support, provided by D.V.A., including pensioning, on the course and present status of the disease.

A survey of the literature was made with reference to the objectives of the study and the methodology to be employed. Previous studies of this particular kind have been, surprisingly, rather rare (1-5, 7-10, 12, 13).

PROCEDURE

The population used was the total number of World War II veterans, namely 118, in British Columbia, diagnosed as, and pensioned for, schizophrenia. Of these, 64 were ambulatory patients, 55 males and 9 females, and 54 were hospitalized, 51 males and 3 females.

Four lines of investigation were: 1. *Psychiatric Status*: The outpatients were examined by one of the psychiatrists and the hospitalized patients by the other psychiatrist. The clinical findings were then summarized on a revised edition of the Malamud and Sands (10) psychiatric rating scale and on an "insight" scale. Inter-psychiatrist (rater) reliability had previously been established as significant ($r=.84$) on an independent, but similar, sample of 30 patients.

The 7 point scale assessed the following 19 functions: appearance, motor activity, responsiveness, aggressiveness, socialization, communicability, thought processes, attention, awareness, association, content, memory, affective reaction, feeling tone, mood, sleep, nutrition, sexuality, and work. The "insight" questionnaire assessed the extent to which the patient understood the nature of his illness, what types of treatment he had received, the name he gave to his illness, and his reactions to pensioning. 2. *Psychological Status*: The Wechsler Adult Intelligence Scale and the Rorschach, scored according to the technique of Buhler, Buhler and Lefever (6), were administered to each patient. 3. *Personal-Family-Treatment History*: These were obtained from the rather comprehensive District and Hospital files, using military, medical and social work data. 4. *Interview of Relatives*: The relatives who had indicated the most interest in the patient over the years were visited and interviewed by a member of Veterans Welfare Services.

RESULTS AND DISCUSSION

The frame of reference for the analysis of the data that was the distribution of scores on the psychiatric rating scale. Comparisons were made between ambulatory and hospital groups, and then between two ambulatory and three hospital subgroups, using chi square and the t. test for all comparisons—A1 and A2, H1 and H2, H2 and H3, A1 and H1, A2 and H2, A and H.

Our first finding from the psychiatric data indicated that the relationship between mental status and ambulatory or hospital status was not a close one; 29.70% of the ambulatory group revealed as much pathology as, or significantly more than, a sizable portion, 74.08%, of the hospital group. Grossly pathological symptoms, namely, hallucinations and/or delusions, were found in as many as 20.31% of the ambulatory group and in only 37.29% of the hospital group. While some of the ambulatory pa-

This project was sponsored by grant No. 14-58, of the Department of Veterans Affairs, to whom we wish to express our thanks.

² Department of Psychiatry and Department of Psychology, Shaughnessy Hospital, Vancouver, B. C.

tients revealed an ability to exercise the judgments and make the decisions of ordinary life by thinking in concrete terms and using habitual responses, careful scrutiny revealed that they continued to suffer from thought disorder. Others had learned to inhibit the expression of their delusions and inappropriate feelings. Still others revealed gross personality distortion and desocialization. The ambulatory group, but most particularly ambulatory subgroup A1, exhibited the greatest degree of insight into : the nature of their illness, the type of treatment they had received, the contribution of treatment towards their improved state, and that their illness was a mental one. The 7.63% of the population who mentioned psychotherapy, acknowledged it in only rudimentary terms. Even our best adjusted patients appear to have only very superficial insight. But what they do express in action, and in one way or another, in words, is that they have developed various self-protective devices, even to the point of repressing mention of the fact that their illness was emotional or mental. The insight they have found useful is the acknowledgment of their limitations.

With respect to the psychological evaluation, analysis of the Wechsler revealed a significant relationship among current level of intellectual functioning, extent of impairment and psychiatric status. The ambulatory group are brighter and less impaired than the hospital group, while ambulatory subgroup A1 reveal the same trend with respect to ambulatory subgroup A2. Some degree of impairment, as measured by vocabulary scatter, verbal-performance discrepancy, and inter-test variability, was found in all of the patients : 29.57% exhibited minimal impairment, 52.18% moderate impairment, and 18.25% advanced impairment. There is every indication that, while a good intellectual endowment may not preclude affliction by the disease, it does provide greater potential for rehabilitation, even when there is continuing thought disorder. The correlation (r) between the Basic Rorschach Score and the psychiatric rating scale was $-.53$, and significant beyond the .01 level of confidence. When the Basic Rorschach Scores were distributed among Buhler's(6) four levels of integra-

tion—Adequacy, Conflict, Defect, Reality Loss—we found : no entries in the initial or Adequacy category ; 14.78% in the Conflict category (with only the ambulatory group contributing to this category) ; 23.48% in the Defect category (17.39% of these were in the ambulatory group) ; the remaining 61.74% in the Reality Loss category (20.87% of these were in the ambulatory group). It is significant that more than 70% of the ambulatory group evidence very tenuous reality testing, *i.e.*, register in the Defect and Reality Loss categories. While all of these patients have been through a period of personality disorganization, comparatively few have regained their premorbid intellectual efficiency or personality stability.

In our third line of investigation, by reviewing historical data, we sought to clarify some of the differences in current reaction-patterns among patients, as evidenced in the psychiatric and psychological findings. We accordingly turned to factors that might be of etiological import, together with data that reflected the course of the disease over the years.

With respect to service history, we could detect no significant trends. Age of enlistment (range : 17 to 51 years, mean : 23.22 years), though coinciding with age of maximum susceptibility to schizophrenia, was not significant. Length of service (range : 3 to 123 months, mean : 33.11 months), *i.e.*, prolonged exposure to stress, did not reveal a significant pattern. Area of service (41.52% never left Canada and only 33.90% served in a zone of operations), *i.e.*, intensity of stress, also proved to be non-significant. Nor were we able to detect the existence, in any significant proportion, of specific precipitating factors, apart from military stress. What aspects of Service life can be construed as having been most contributory ? Anxiety to an intolerable degree, may have been aroused by separation from familial and environmental supports. Service may also have demanded an ability to form types of relationships beyond these persons' range of adaptability. All we can say is that 77.97% of our group initially broke down during Service, for an overwhelmingly large proportion of these the break was psychotic and quite acute.

Secondly, we reviewed developmental

history. Pathogenic parental attitudes (rejection, extreme discipline, extreme independence, extreme indulgence and extreme overprotection) were found in only 44.07% of our population. Wahl(13) also reports pathogenic parental attitudes in only 50.3% of his group. Relationships with siblings were inappropriate in 31.51% of our group. Caldwell(7), however, reports that 60% did not evidence strong family ties. There is some possibility that relatives who provided the histories in our group have been unduly defensive or not sufficiently critical. Death, divorce or separation of parents before the end of adolescence was found in 31.36% of our group as compared to Wahl's (13) finding of 41%. In any event, we found no significant differences among our subgroups with respect to the above three factors. Like Caldwell(7) and Wahl(13), we could not demonstrate readily discernible conflict in early relationships in every patient under investigation.

Thirdly, we searched for signs of predisposition towards mental illness and premorbid personality patterns. The incidence of psychiatric history in immediate family appears to be much higher in our study than in the population as a whole—30.15% revealed mental illness in the immediate family (parents and siblings). These figures are probably higher than Caldwell's(7) stated 33%, as he included under immediate family, grandparents, uncles and aunts. However, there were no differences among our subgroups with respect to predisposition. Data about premorbid personality were only available for 60.17% of the patients and for somewhat more than two-thirds of these we could not find evidence of schizoid or pronounced introverted trends. Our findings, as well as the research of Bellak and Parcell(2), Caldwell(7), Ripley and Wolf(12), do not reveal a readily recognized, consistent pre-schizophrenic personality.

Fourthly, we reviewed educational and occupational history. The mean educational level was 9.55 grades, and the range from grade 3 to 5th year university. Educational level was significantly higher for the ambulatory compared to the hospital group and for ambulatory subgroup A1 compared to ambulatory subgroup A2. Premorbid oc-

cupational level, but not work stability, was significantly higher for the ambulatory compared to the hospital group. The effect of the illness on the ambulatory group has been downward vocational mobility and decreased work stability.

Fifthly, we reviewed treatment history. All of the veterans in our study have been hospitalized for their mental illness. The last decade and a half, for many, has been a series of exacerbations and remissions; for others, a single episode lasting 16 years without remission. The group has had on the average 3.91 "breakdowns" necessitating hospitalization, and has spent on the average 74.07 months (range was 2 to 192 months) in hospital. Outpatient contact has until recently been restricted to some of the better-integrated patients. With respect to treatment *per se*, the relationship between type and extent of treatment and present status remains unclear. While the group as a whole has been exposed to rather intensive treatment, the hospital group had a greater variety, including psychosurgery, somatotherapy, chemotherapy, and milieu therapy. There is, however, little indication that psychotherapy played a significant role in the treatment of these patients. Though the ataractic drugs have undoubtedly played a significant role in stabilizing many of our patients, and most particularly in facilitating the release of some long-term cases, the overall effect of the drugs, for the group as a whole is unclear as yet. With respect to the type of schizophrenia, 19.49% were classified as simple, 58.48% as paranoid, 13.56% as catatonic, and 8.47% as hebephrenic. But we found no relationship between type of schizophrenia and our subgroupings.

Our fourth line of investigation for clarifying differences in current reaction-patterns of patient focused on the relatives—their attitudes, expectancies, and day to day treatment of the patient. Data, based on interview and observation of the home setting, indicate that the general health, mental stability, competency of, and general standard of living for, an overwhelming proportion of the informants is not out of keeping with the community at large. In contrast to the hospital group, relatives of the ambulatory group, and more particular-

ly ambulatory subgroup A1, are better informed about mental health and mental illness, are more insightful about the patient's condition and limitations, and are more optimistic about the patient's future. At the present time, 78.12% of the ambulatory patients are living with relatives, and receiving day by day support; more than half of the remainder, though living apart from relatives, are still within the orbit of the family influence. While one of the residual effects of this disease is to decrease the range of relationships, even for the better integrated, schizophrenia does not preclude or incapacitate individuals from establishing and maintaining enduring relationships. Granted that the relationship is often with a parent (50% of the ambulatory group live with a parent) and in our groups most often with a mother, where pathological behaviour may be condoned or even reinforced, this has important implications for the treatment of schizophrenia. Furthermore, 21.19% of the group under review are married, and almost all contracted their marriage after their mental illness was manifested. Two-thirds of the married patients are ambulatory, and in fact in ambulatory subgroup A1. Interestingly, the marital adjustment is defined as good in 78% of our cases; 72% have children; and the attitude towards the children is more or less appropriate in 85% of these cases. With respect to those patients residing with a parent, if the parent should become incapacitated, a considerable number of patients would, in all probability, decompensate, or their adjustment would be lowered to the point where they would require some form of custodial care or close support from the community.

Inter-related to the emotional support that has been provided by relatives, is the support made available by D.V.A. pensioning. An analysis of patients' and relatives' attitudes reveals that 84.38% of ambulatory patients, as well as 85.85% of relatives of both ambulatory and hospital patients, expressed appreciation of pension, both with respect to the economic security, the treatment, and the interest that have been provided. Pensioning also permits certain patients to hold down less-challenging jobs, or to remain nearly self-supporting with

part time work, thus protecting them from one source of stress. Pensioning also often qualifies relatives' attitudes towards the patient and his illness in a positive manner, thus enhancing and reinforcing relatives' support of patients. For the group under review, there is every indication that the benefits from pension have more than offset the adverse effects that this might have had on patient's motivation to work. It is also most probable that if D.V.A. did not contribute to the economic and therapeutic support of these patients, the responsibility would have to be assumed by some other agency in the community.

One trend was discernible in our analysis of the data—the trend towards alteration in adjustment potential or residual impairment. In order to document this more explicitly, we focused on only the ambulatory group; and to arrive at an estimate of impairment from the premorbid level for this group, we took into consideration the psychiatric data, the psychological data, employment status and their sphere of relationships. Weights were assigned to the distribution of scores on the psychiatric rating scale, and scale of insight; to the index of inefficiency on the WAIS, and to the levels of integration on the Rorschach; to the extent of vocational mobility and instability; and to the social interaction or sphere of relationships. A composite score was, therefore, available for each patient. The scores were then distributed among categories which we designated minimal, moderate, advanced, and analyzed by means of chi square. Our index of impairment revealed: 1. Half of the ambulatory patients show moderate impairment, with the remainder being almost equally divided among the minimal and advanced categories; 2. Only one-third of the ambulatory subgroup A1 show minimal impairment, the remainder of this subgroup exhibit more severe impairment. None of the ambulatory subgroup A2 were found in the minimal category, and two-thirds were in the advanced impairment category; 3. There is a significant relationship between level of adjustment and type of supporting figure. Patients residing with a spouse tend towards the minimal-moderate end of the impairment range (11 of the 15 in the minimal

category are living with a spouse), whereas those living with a parent, or alone, tend towards the moderate-advanced end of the range.

How might we account for the fact that a sizable portion of the hospital group evidenced considerably less pathology than some of the ambulatory patients and yet remained institutionalized? Few of these patients would be regarded as dangerous to themselves or to the community at large. Our observations of these patients, and the data on hand, suggest that many remain in hospital because of two factors. The first is the absence of an interested family member to either pressure for release or assume responsibility for the patient if this has been suggested. Within the hospital group, 50% either "seldom" or "never" receive a visitor—all but one of the patients who are never visited are in the less-severely disabled hospital subgroups. Dependency appears to be the other main factor that is keeping some of these patients in the hospital. Many patients find that their dependency needs are most adequately satisfied by the current medical-social arrangement of the hospital.

CONCLUSIONS

We were not able to demonstrate significant trends or relationships between the onset and course of the disease on the one hand, and the present status on the other, in a group of schizophrenics, many of whom might be classified as chronics. Age at breakdown, acute onset of symptoms, developmental factors, in themselves or in toto, do not appear to be reliable predictors as to the long-term picture of adjustment for such a group. Intellectual endowment and education, which are themselves highly correlated, were found to be predictive indices as to adjustment potential. The most important factor, however, was that of family support—support that took the form of continued responsible acceptance of the patient. As a matter of fact, whether a patient was hospitalized or remained in the community often depended on the extent of direct social support. We suggest that prognosis in schizophrenia depends as much on the unfaltering support of the relatives as on symptomatology or extent of treatment. If direct social support by the family is the

necessary determinant for a more adequate and stable level of adjustment, and indeed it appears to be, indirect support—economic, treatment, interest—by D.V.A. is a secondary, but important factor for continuing remission. Long-term involvement with D.V.A. also qualifies relatives' attitudes towards the patient and his illness in a positive manner, thus reinforcing relatives' support of patients. At least in the group we are investigating, it is not surprising to find that the disease has been lengthy and self-limiting, and that patients have been left with some degree of residual impairment. We must emphasize, however, that chronicity diminishes, but does not destroy the patient's capacity to enter into meaningful human relationships. We must further emphasize that treatment responsibility should extend beyond the period when the patient is floridly psychotic. Many patients in fact require lifelong "rehabilitation," and if influences from outside of hospital have as much, and at times more, to do with rehabilitation than treatment within the hospital, then family and community should share in this rehabilitation programme from the very onset of the disease. There is also firm reason to indicate that many a chronic schizophrenic patient is able to learn, by progressive maturation, to be self-supporting, at least partially, in the community, when given the opportunity for a continuing rehabilitation programme.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

EFFECTS OF A DRUG ON THE BODY ODOR OF THE CHRONICALLY MENTALLY ILL

CARL GOULDMAN, M.D.,¹ AND AVONELL RUTHERFORD, R.N.²

Sch-6673,³ which is similar in chemical structure to Trilafon, was evaluated as a tranquilizer. After the study⁴ was completed, 3 patients were kept on the drug because of its good effects. One of these patients had a marked body odor which disappeared completely while on Sch-6673 and re-appeared when he was placed on a different drug.

Eighteen patients, age 22-55 (6 males, 12 females), were then chosen because of their unpleasant odor and were started on Sch-6673 to determine the drug's deodorizing effect. The intent of the study was to conceal its purpose from the ward employees. Diagnoses: schizophrenia 9, mental defect 2, C.B.S. 5, alcoholics 2.

METHOD

The patients were divided into 2 groups according to sex. The female group remained on drug during the course of the study to determine if the effect was lasting. The male group was placed on the drug until a change in their odor became apparent, then the drug was discontinued until the odor reappeared and were placed on the drug again until deodorized.

No change was made in the patients' diet,

the frequency with which they were bathed or their clothing was changed. They remained on the same wards. Three research personnel made a daily check of the patients' odor by standing close to them during an interview. An additional check of the odor was made while taking the patient's blood pressure and having him raise and lower his arms.

The initial dosage was two 50 mgm. tablets daily by mouth for 15 days, then a 50 mgm. was given every other day for 22 days. The change in odor appeared to be dose-related. As a rule the patient remained deodorized for 3 days after the drug was stopped.

RESULTS

Only one patient, a schizophrenic female who developed epileptiform seizures, was dropped from the study.

By the 12th day the characteristic body odor was no longer apparent in 14 of the 17 patients. This change was noted in 4 patients after 3 days, in 6 more after a week and in 4 others at the end of 12 days. Ten of these 14 patients remained odor free for 16 to 22 days. In the other 4, the change was intermittent, i.e. the odor was evident on some days and absent on others.

The effect did not appear to be sex-related. In those male patients whose body odor disappeared while they were on the drug, the odor re-appeared when the drug was stopped and disappeared when it was re-started.

DISCUSSION

Our impression is that the effect of the drug was more pronounced in schizophrenics than in the other patients. If this is correct, and if the perspiration of certain

schizophrenics has a distinct odor,⁵ then that odor may be the product of a characteristic metabolic disturbance which might be modified by the use of Sch-6673.

This report is preliminary and we are attempting to check these observations by making more exact determinations of

⁵ Smith, Kathleen, and Sines, Jacob O.: Arch. Gen. Psychiat., 2 : 184, Feb. 1960.

changes in odor, and non-psychotic patients are also being included in another group. We are aware that "bad" or "schizophrenic" odor is a highly subjective matter and that it is no longer fashionable to identify an illness by its odor. However, if a group of schizophrenic patients who "smell alike" can be identified and altered, then other more measurable variations may be sought.

THE USE OF A NEW ULTRA-SHORT-ACTING INTRAVENOUS ANESTHETIC IN SHOCK THERAPY

WILLIAM KARLINER, M.D.,¹ AND LOUIS J. PADULA, M.D.

Brevital Sodium (methohexital sodium²) is a new intravenous barbiturate anesthetic. It belongs to the oxybarbiturates which are known to be less toxic and ultra-short-acting anesthetic agents. Stoelting(2) reported that Brevital "proved three times as potent as pentothal sodium and 4½ times as potent as surital sodium."

Many psychiatrists use barbiturate anesthesia in conjunction with succinylcholine chloride modified electroshock therapy. Such an anesthesia helps to allay the patient's apprehension and fear of treatments. Moreover, this anesthesia eliminates the awareness of the unpleasant side-effects of succinylcholine chloride, such as muscular fasciculations and feelings of suffocation. Friedman(1) used Brevital as an intravenous anesthetic agent for electroshock in 72 patients. He stated that "the anesthetic efficiency, safety, rare incidence of complications, and ease of administration compared favorably with the commonly used thiobarbiturates."

The search for an improved method of treatment motivated us to clinically explore this new anesthetic in electroshock and Indoklon convulsive therapy. The high potency of Brevital and its ultra-short-acting duration necessitate a different technic of administration. Atropine sulfate 1/75 grain is given subcutaneously 30 minutes before the scheduled treatment. However, when

ever indicated, atropine may be given intravenously through a 22-gauge needle immediately preceding the treatment. The needle is left in situ and after removing the syringe containing the atropine, a 10 cc. syringe containing a 1% solution of Brevital (50 cc. distilled water added to bottle containing 500 mg. Brevital) is connected to it. Five to 10 cc. of Brevital solution (50 to 100 mg.) is usually adequate to anesthetize the patient. We found the rate of injection of one cc. of 1% solution in 5 seconds optimal. If injected too rapidly, more Brevital will be required, and transient apnea may be produced. The Brevital syringe is then removed and succinylcholine chloride is administered rapidly. Thirty seconds after termination of the injection of the muscle relaxant, the electric stimulation is given. In Indoklon convulsive treatment, the mask is tightly placed on the face and the bag gently squeezed as soon as the injections are finished.

Because of Brevital's ultra-short duration, the patients awaken much faster and are able to leave the treatment room much earlier than they could when thiobarbiturate anesthesia was used. It is also possible to treat a larger number of patients in a shorter period of time. In our series, one-third to one-half the amount of barbiturate was required to obtain adequate anesthesia. The small amount of Brevital used for anesthesia in conjunction with convulsive treatments, has hardly any ill-effect on the respiration of the patient. On the other hand, the larger amounts of thiobarbiturates

¹ 20 Franklin Rd., Scarsdale, N. Y.

² The Brevital Sodium used in this study was supplied by the Lilly Research Laboratories, Indianapolis, Ind.

which were required to obtain adequate anesthesia in electroshock, were a hazard because they increased the apnea which generally followed electroshock. We were also able to treat "poor risk" patients with cardiovascular disease, whom, in the past, we had been forced to treat without barbiturate anesthesia.

We gave Brevital anesthesia to 69 patients for succinylcholine modified electroshock or Indoklon convulsive treatments.³ Forty-seven patients had 158 electroshocks, and 22 had 105 Indoklon treatments. Two of our patients who suffered a moderately severe laryngospasm with Pentothal anesthesia did not have this side-effect when Brevital anesthesia was substituted. Some patients who complained of an unpleasant taste when given Pentothal anesthesia did

³ All treatments were given at West Hill Sanitarium, Riverdale, N. Y.

not notice this sensation with Brevital. Most patients showed less salivation with this oxybarbiturate anesthesia; thus the risk of aspiration was decreased. In some patients, Brevital reduced the electrical threshold, thereby enabling us to obtain a grand mal response with less voltage and time.

We found Brevital Sodium anesthesia to be the most useful anesthetic agent for electroshock and Indoklon convulsive therapy. It is ultra-short-acting, more powerful, and less toxic than other barbiturate anesthetics heretofore used. It is safe and easy to administer, and its use in convulsive treatment is recommended.

COMBINED PHARMACO-FEVER TREATMENT WITH IMIPRAMINE (TOFRANIL) AND TYPHOID VACCINE IN THE MANAGEMENT OF DEPRESSIVE CONDITIONS

H. E. LEHMANN, M.D.¹

There are three major limitations of the pharmacotherapy of psychiatric depressions: 1. The time lag between commencement of therapy and onset of therapeutic effect; 2. Owing to the former, difficulties in the management of acutely suicidal patients; and 3. The ineffectiveness of pharmacotherapy in a proportion of refractory cases.

In an attempt to overcome some of these limitations, artificially induced pyrexia was combined with the administration of imipramine (Tofranil). The rationale for this approach was based on the hypothesis that the therapeutic effectiveness of the drug was to some degree a function of its availability in the target organ and consequently depended on the blood-brain barrier which controls the access of pharmacological agents to the central nervous system. Electroconvulsive therapy and fever are two physical treatment methods which are

known to lower the blood-brain barrier and to facilitate the passing of chemical substances from the circulatory system into the brain and the surrounding cerebrospinal fluid (1, 2, 3). In this connection one may speculate that the "shock-saving" effect of imipramine which has been observed in patients receiving both pharmacologic and convulsive therapy may also be interpreted as a "drug-saving" effect of electroconvulsive treatments. In other words, a few induced convulsions may rapidly lead to therapeutic concentrations of the drug in the central nervous system through lowering of the blood-brain barrier.

Since fever therapy is a much less drastic procedure than electroconvulsive treatment in regard to its physiological and psychological effects, we chose it as the accelerating physical factor in the pharmacotherapy of depressive states. We had observed the usefulness of medically induced pyrexia many years ago in facilitating the therapeutic action of thiamine chloride

¹ Verdun Protestant Hospital and McGill University, Montreal, Canada.

in cases of atrophy of the optic nerve. We had also been impressed with the beneficial though transient effects of fever therapy in certain cases of schizophrenia. Whether induced pyrexia actually increases the concentration of imipramine in the CSF has not yet been directly tested because we know of no reliable method to determine the amount of imipramine in the CSF accurately.

In addition to the physiological rationale we intended to harness the empirically established anxiety-reducing effect of any type of fever in the therapeutic management of agitated and suicidal patients. Finally, we expected that the continuous observation of a suicidal patient would be much easier if the patient was confined to bed and required some nursing care because of a mild physical illness.

Pyrexia was induced with typhoid fever vaccine administered intravenously. Twenty-five million killed bacteria were injected the first time. Our vaccine preparation contained 250,000,000 killed bacteria per 1.00 cc. We diluted 1.0 cc. of vaccine in 9.00 cc. of distilled water and injected 0.1 cc. of this dilution into the cubital vein. The second injection consisted of 50,000,000 bacteria, the third of 100,000,000 and the fourth of 200,000,000. Injections were given on successive or alternate days. According to the initial reaction the second, third and fourth doses were sometimes varied above or below the usual progressive increase. Three to four treatments were given in most cases. The patient's temperature begins to rise 2 to 3 hours after the intravenous injection of vaccine. Sometimes an initial chill is observed and the patient may complain of headache. The temperature, as a rule, does not rise above 103° and more frequently reaches only 101-102°. It usually recedes to the normal level within 5 hours. Some patients are quite resistant to the pyrexia producing effect of the vaccine and require higher doses. Imipramine in doses of 50 mg. is given intramuscularly three times a day concurrently with the fever therapy.

Our results were encouraging. We treated 26 depressed patients with the combination of imipramine and artificially induced pyrexia. All patients were suffering from functional affective disorders, i.e., manic-

depressive, involutional or reactive depressions. Our criteria for a successful response were that the patients who had not received imipramine previously showed significant improvement within the first week of the combined imipramine-fever treatment or that improvement was noted within 2 weeks in those patients who had already been treated with the drug alone for 3 weeks without having shown any favourable change. In 15 of the 26 patients (58%) the combined pharmaco-fever treatment yielded these special criteria for a successful response. However, a successful response was more frequently obtained in those patients who had previously been refractory to imipramine therapy than in patients who had just been started on the drug. In other words, the combined pharmaco-fever treatment proved useful in cases who had previously been unresponsive to the drug alone but it could not be relied upon to the same extent to shorten the duration of the treatment. In a number of cases, however, distinct improvement was noted within a day or two of the combined therapy.

This was particularly gratifying in two out of three acutely suicidal patients in our series. One of these, a young woman, had been transferred to our hospital because she could no longer be managed in the psychiatric department of a general hospital where after a number of electro-convulsive treatments had been given she still persisted with the most determined attempts at self-destruction. On the first day in our hospital she tried to commit suicide on two occasions. She was immediately placed on pharmaco-fever therapy with imipramine and typhoid vaccine and her agitation and suicidal tendencies subsided with the first pyrexia. She was discharged recovered three weeks after admission. The other suicidal patient had been extremely tense and had been of considerable concern to the nursing staff because of several near-miss suicidal attempts in the past. While she still remained depressed for several weeks her tension and her suicidal drive were visibly reduced after the first two combined fever treatments and she no longer presented any problems after 4 treatments. Imipramine medication alone was then continued for

several weeks until complete remission had occurred. The third of our acutely suicidal patients did not improve and responded later to ECT.

It is our impression that the combined pharmaco-fever treatment with imipramine and typhoid vaccine merits a clinical trial in all cases of depression who present special problems because they fail to respond to the drug alone or because they are unusually tense and suicidal.

SUMMARY

Imipramine (Tofranil) therapy and artificial pyrexia obtained through the intravenous administration of typhoid vaccine in gradually increasing amounts were combined in the therapeutic management of special clinical problems encountered in depressed patients. Shortening of the time lag between the start of treatment and first significant improvement, a final favourable response in patients who at first had proved refractory to the drug and therapeutic control of acutely suicidal patients were the

criteria for successful responses. These special criteria were met in 15 of our 26 patients (58%) subjected to pharmaco-fever therapy. It is assumed that the mechanism which contributed to a favourable response include the physiological lowering of the blood-brain barrier with a resulting increase of drug concentration in the target organ. On the psychological side, the unspecific anxiety-reducing effects of pyrexia are noted as well as the facilitation of clinical and nursing management of acutely suicidal patients if they are confined to bed with a recurring fever of moderate degree.

A COMPARISON OF PERPHENAZINE, PROKETAZINE, NIALAMIDE AND MO-482 IN CHRONIC SCHIZOPHRENICS

NAUTTAM J. KOTHARI, M.D.,¹ JOHN C. SAUNDERS, M.D.,¹
NATHAN S. KLINE, M.D.,¹ AND JOSEPH A. GRIFFEN, M.D.²

Since the success of reserpine and chlorpromazine in institutionalized psychotic patients, new phrenotropic agents have become available for therapeutic trial. The initial encouraging report of the beneficial effect of iproniazid on blocked, regressed and apathetic schizophrenics, has initiated synthesis of new chemicals for clinical trial as psychoactivators. Many of these chemicals have the same property as iproniazid, that is, to inhibit monoamine oxidase and alleviate depression(1). Since the reports of the psychopharmacotherapeutic properties of available drugs are of wide range and varied, we have studied the pheno-

thiazines, perphenazine and proketazine, and the hydrazides, nialamide and MO-482 (1-1(2-phenylisopropyl)-1-methyl hydrazine).³ This evaluation was to determine the relative clinical efficacy of a new phenothiazine (proketazine) and a new hydrazide (MO-482) with compounds of known activity. In addition, we desired to better characterize the psychotic symptoms that may be alleviated with these two types of psychopharmacological agents, phenothiazines and hydrazides.

¹ Research Facility, Rockland State Hospital, Orangeburg, N. Y. and College of Physicians and Surgeons, Columbia University, New York City.

² Rockland State Hospital, Orangeburg, N. Y.

³ The perphenazine used in this study was supplied as Trilafon by Schering Corporation, Bloomfield, N. J.; the proketazine by Wyeth Laboratories, Philadelphia, Pa.; the nialamide was supplied as Niamid by Chas. Pfizer & Co., Inc., Brooklyn, N. Y. and MO-482 (1-1(2-phenylisopropyl)-1-methyl hydrazide) by Abbott Laboratories, North Chicago, Ill.

METHODS

One hundred schizophrenics with an average duration of 10 years of hospitalization, were selected for this study. They were divided into 4 groups of 25 each. In each group there were about an equal number of (a) schizophrenics with Bleuler's secondary symptoms of delusions, hallucinations or dereistic behavior and (b) schizophrenics with Bleuler's primary symptoms of autism with detachment from reality, disturbances of affectivity and associational deprivation. Each group received either perphenazine, proketazine, nialamide or MO-482. The patients initially received the minimal oral therapeutic dose. The dosage was raised twice a week, either to an optimal beneficial level or to the maximal below that of untoward reactions. The daily therapeutic range was 16 to 64 mg. perphenazine, 50 to 600 mg. proketazine, 50 to 600 mg. nialamide and 10 to 100 mg. MO-482. If side effects occurred, the dose was reduced to a level at which they disappeared. After 12 weeks on this therapeutic range, the medication was gradually withdrawn.

RESULTS

The blood pressure of each patient was taken weekly during the treatment. A fall of 10 to 20 mm. Hg. in diastolic pressure was observed in 16 patients each on perphenazine and proketazine, in 9 patients on nialamide and in 12 on MO-482. One patient on perphenazine, 2 on proketazine and 2 on MO-482 had a fall of 20 to 30 mm. Hg. The remaining patients had a fall of less than 10 mm. Hg.

A sedative action by the phenothiazines or a feeling of well being by the hydrazides, was recognized as slight improvement. A reduction of hypermotility of thought and behavior with phenothiazines or a partial contact with reality and an interest in their environment with the hydrazides was interpreted as moderate improvement. With either group of drugs the disappearance of disorders of thought and affect, accompanied by integration of personality, signified marked improvement.

Improvement was observed in 11 patients on perphenazine, 11 on proketazine, 11 on nialamide and 7 on MO-482. Moderate to marked improvement was observed in 7

patients on perphenazine, 8 patients on proketazine, 3 on nialamide and 5 on MO-482. Perphenazine had slight to marked effect on the secondary symptoms of 10 patients and 1 patient with primary symptoms became worse. Proketazine produced slight to marked improvement in 7 patients with secondary and 4 patients with primary symptoms. Nialamide and MO-482 had the most beneficial effect on the primary symptoms of 10 and 5 patients and on secondary symptoms of 1 and 2 patients respectively. Three patients with secondary symptoms became worse with MO-482. One patient receiving 50 mg. proketazine died after 8 weeks of treatment. Autopsy revealed generalized arteriosclerosis and ischemic heart without histopathological evidence of drug reaction. Five patients on MO-482, 3 on nialamide, 1 on proketazine and 1 on perphenazine became disturbed. With reduced medication, they became quiet and showed clinical improvement. Two patients on proketazine became akathic. Rigidity appeared in 1 patient on perphenazine and 3 on proketazine. One patient on proketazine presented signs of generalized tremor and 1 patient receiving perphenazine complained of drowsiness. A syncopal attack was observed in 2 patients receiving MO-482.

DISCUSSION

The results indicate that the therapeutic efficacy of proketazine is about the same as that of perphenazine; the number of patients showing improvement with nialamide is larger than that with MO-482, but the clinical efficacy from nialamide is less than that observed with MO-482. Reserpine and phenothiazines in schizophrenics have been observed to counteract disorders of thought, hyperactivity or both(2, 3). Perphenazine and proketazine have beneficial effect in patients with delusions, hallucinations or with dereistic behavior. Nialamide and MO-482 are effective in disturbances of affectivity, autism with detachment from reality, associational deprivation and ambivalence of affect and will. Phenothiazines fall into a generalized category of psychoinhibitors and hydrazides into that of psychoactivators. Phenothiazines have sedative as well as antipsychotic activity. By nature of this dual activity, these drugs reduce

hypermotility of behavior, aberrant thought, and the accompanying emotional overflow (4). The monoamine oxidase inhibiting hydrazides have more energizing effect than stimulating and thereby induce a feeling of well being (eudaemonia). The psychoinhibitors are useful in alleviating hyperactivity, euphoria, delusions and hallucinations which are the side effects of the psychoactivators.

Phenothiazines, reportedly having high incidence of side effects, are among the most effective psychotherapeutic agents; our impression is that hydrazides follow the same pattern. Two of the 3 patients on nialamide and 2 of the 5 on MO-482 who showed secondary symptomatic disturbances improved after the discontinuance of treatment.

There was no correlation between the dosage and degree of improvement since patients require individualization of therapy.

SUMMARY

Of 25 chronic schizophrenics in each group on perphenazine and proketazone, 11

patients on each drug showed improvement. The patients with delusions, hallucinations and hyperactivity had the maximal benefit from these psychoinhibiting drugs. Of 25 chronic schizophrenics in each group, 11 improved with nialamide and 7 with MO-482. Seven patients on perphenazine and 8 on proketazone improved either to a moderate or marked degree. Moderate to marked improvement was seen in 3 and 5 patients on nialamide and MO-482 respectively. Apathetic and autistic patients had the maximal benefit from the psychoactivating drugs. These drugs are relatively safe as no serious untoward clinical or laboratory results were observed.

ATROPINE-LIKE POISONING DUE TO TRANQUILIZING AGENTS

HARBHAJAN SINGH, M.D.¹

Atropine-like poisoning as a side effect of tranquilizers has been mentioned, from time to time, by some drug companies. Mahrer, Bergman, and Estren² reported an atropine-like poisoning reaction in a patient treated 6 weeks with Pacatal and Compazine. The reaction was concomitant with the rise of atmospheric temperature and humidity.

Mild anticholinergic reactions such as constipation, blurring of vision, dryness of mouth and skin, are very common side-effects of tranquilizers. The severe anticholinergic reaction (atropine-like poisoning reaction) in the case mentioned above, was thought to have resulted from synergistic reaction of Pacatal and Compazine.

We have recently observed such atropine-like reaction in a patient treated with Nardil (phenylethylhydrazine) and Tofranil (imipramine hydrochloride).

C. V., a 55-year-old white female was admitted to our hospital for the third time in May 1960, because of depression, self depreciation and guilt feelings. Her case was diagnosed involuntal depressive reaction. On May 10, she was put on Nardil—15 mg. q.i.d. but there was no significant response. On May 23, she was put on I.M., Tofranil—25 mg. t.i.d. Twenty minutes after receiving the first injection, the patient became agitated, tremulous and delirious. This was followed by generalized clonic convulsions and hyperthermia of 105.8° F. Physical findings revealed flushed face, warm dry skin and dry mouth. Pupils were dilated and not reacting to light, pulse 200/min., respiration 30/min. There was

¹Chief of Admissions and Intensive Treatment area, Mental Health Institute, Independence, Iowa.

²*Am. J. Psychiat.* : Oct. 1958.

no response to pin prick or other stimuli. Other physical and neurological findings were negative.

Patient was treated with Aspirin, I.M. sodium amytal, and I.V. fluids. She was also covered with a wet sheet upon which 2 fans were directed. In 4 hours the temperature came down to 100.5° F., the convulsions stopped and patient started to respond. After 12 hours her temperature was down to 99° F., her pupils were still somewhat dilated and did not react to light until 48 hours later.

Laboratory studies of urinalysis and CBC, on admission and on 2 consecutive days after the reaction, were within normal limits. An EEG taken 2 days following the reaction, was normal.

DISCUSSION

Since it is not yet fully known how various tranquilizers and energizers work

synergetically, it is difficult to ascertain if the reaction (a) was due purely to Tofranil which, though an energizer, has a chemical structure similar to phenothiazines, (b) if it was due to synergetic action of Tofranil and Nardil (monoamine oxidase inhibitor) or (c) if it was due to any idiosyncrasy on the part of the patient.

Two years ago we had another patient who developed a similar reaction to a combination of Pacatal and Sparine (both phenothiazines). The case was not reported.

The present case is being reported in order to caution the simultaneous use of various tranquilizers and energizers and to emphasize the need of further research in this area.

CLINICAL AND THEORETICAL OBSERVATIONS ON PHENELZINE, (NARDIL¹), AN ANTIDEPRESSANT AGENT²

CAPTAIN ROBERT A. COLE, AND CAPTAIN MYRON F. WEINER³

Apathy, anergy, withdrawal, and depression are symptoms of many functional and organic central nervous system disturbances. Frequently, psychotherapy alone does not produce sufficient, or sufficiently rapid improvement. In this situation, drug therapy seems to be a logical primary or adjunctive treatment.

Phenelzine inhibits the *in vivo* action of monoamine oxidase, an enzyme found in greatest concentration in brain tissue in the hypothalamus and brain stem. Monoamine oxidase oxidizes a number of monoamines, including serotonin, at a rapid rate and has a distribution in the brain corresponding to that of serotonin. Monoamine oxidase inhibitors have been of value in states characterized by psychic and physiologic depression. Although there is no unequivocal

proof, it might be postulated that a state of relative serotonin deficiency exists in certain areas or pathways of the brain. Rhythmic, pulsatile activity has been seen in oligodendrocytes in tissue culture. There is evidence to indicate that oligodendrocytes may participate in the removal of CO₂ from the environment of the active neuron, that their function may be related to the formation and maintenance of myelin, or that they may act as "insulators" of synaptic areas on the surface of neurons. These data indicate that oligodendrocytes may be important in the process of active neural conduction. The rate of pulsation of oligodendrocytes in tissue culture increases when serotonin is added to the culture medium. Reserpine, which reverses or counteracts many of the physiologic effects of serotonin, has been known to produce depressive symptoms. Reserpine-like substances decrease the rate of pulsation of these cells, thus demonstrating a physiological activity correlating with a corresponding change in psychological activity.

The ability of phenelzine to "energize" apathetic patients and to counteract depres-

² Presented February 5, 1960, at the Third Annual Meeting of Air Force Internists and Allied Specialists, USAF Hospital, Lackland, Lackland Air Force Base, Texas.

This paper represents the personal viewpoints of the authors and is not to be construed as a statement of official Air Force policy.

³ Psychiatry Service, USAF M.C., USAF Hospital, Lackland, Tex.

sion was evaluated clinically by the authors. On the basis of the signs and symptoms of apathy, anergy, withdrawal, and depression, 31 patients were selected. Included in the group were 14 cases of neurotic depression, 4 cases of chronic brain syndrome with depression, 2 cases of involutional melancholia, 8 depressed schizophrenics, and 3 non-depressed schizophrenics. There were 14 males and 17 females, both inpatients and outpatients, ranging in age from 17 to 59. The mean duration of symptoms was 15 months, with a range of from 1 week to 6 years. Periodic physical and mental status examinations, liver function studies, and routine hematologic studies were done. The degree of improvement was estimated both clinically and by the subjective reports of the patients. The drug was administered for periods up to 6 months in doses ranging from 15 to 45 mg. per day. Usually, 15 mg. was given t.i.d. for 1 to 4 weeks, followed by a gradual reduction to a maintenance dosage of 15 mg. per day. No external controls were used. Many of the patients served as their own controls, having previously undergone prolonged trials of therapy.

Sixty-eight per cent of the entire group showed improvement. In general, some signs of improvement were shown during the first week of treatment. The symptoms of withdrawal, anergy, apathy, depression, weight loss, anorexia, agitation, somatic complaints, and insomnia were rated individually. With the exception of agitation, each symptom showed improvement commensurate with the overall rate of improvement. There was no correlation between duration or severity of symptoms and response to phenelzine. None of the non-depressed schizophrenics improved. No abnormality of hematologic or liver function studies occurred. Side effects consisted of one case of marked euphoria, two cases of severe agitation, one case of transient severe headache, one case of transient insomnia, one case of a single missed menstrual period, one case of transient ankle edema, one case of postural hypotension and a "drugged" sensation, and 4 cases of a spontaneous decrease in smoking. The case of euphoria responded to a reduction in dosage. Increase in agitation generally responded to chlorpromazine, 100-200 mg. per day.

A COMPARATIVE CONTROLLED STUDY WITH CHLORDIAZEPOXIDE¹

MARSHALL E. SMITH, M.D.²

Three distinct studies were undertaken with a new psychotherapeutic agent, chlordiazepoxide, in the treatment of psychotic and/or psychoneurotic patients. The first, a pilot study on 10 chronic schizophrenic patients, established the drug's safety and calming effect with a lessening of anxiety, and provided information as to dosage and onset of action.

With this knowledge the second study was initiated, a comparative blind evaluation employing 3 groups of 15 patients each, matched as to age (average 41 years), duration of illness (average 12.5 years) and predominant symptomatology (chronic schizophrenia in 37 and manic-depression in 4).

Group A received placebo; Group B, chlorpromazine; Group C, chlordiazepoxide. Two patients from Groups B and C were lost from the study for reasons not connected with drug administration. Medications were identical in appearance. Initial dose was one capsule (50 mg. of active material) t.i.d. with increases of one capsule every three days until a total of 12 to 14 capsules per day was reached. Increments depended on therapeutic response and absence of side effects. The study lasted for 14 weeks. Evaluation was based on general impressions of the observers and on a rating behavior scale.

Five categories were formulated to indicate results of treatment: maximal—complete disappearance of symptoms and ability

¹ Librium, Hoffmann-La Roche Inc., Nutley, N. J.

² 124 Whitfield St., Guilford, Conn.

to participate in the hospital treatment program; moderate—partial disappearance of psychotic symptoms and change in behavior; minimal—no change in symptoms but partial change in behavior; no change; and worse—psychotic symptomatology more apparent and behavior more uncontrolled.

Results were maximal in 1 patient receiving chlordiazepoxide; moderate in 1 patient receiving chlorpromazine and 2 who received chlordiazepoxide; minimal in 5 of the chlordiazepoxide group. Thus improvement occurred in 8 patients on chlordiazepoxide therapy, 1 patient on chlorpromazine therapy and none of the patients on placebo medication. There was no change in 5, 8 and 5, respectively, in Groups A, B, and C. Ten patients became worse on placebo, 4 and 2 respectively on chlorpromazine and chlordiazepoxide.

Side effects in patients who received chlorpromazine in doses above 400 mg. daily were: extrapyramidal stimulation in 4 and ataxia in 3. In patients receiving chlordiazepoxide in doses above 600 mg. daily (20 times the recommended dose), extrapyramidal stimulation was seen in 4 and ataxia in 2, while 2 patients experienced hypermotor activity on 150 mg. daily. Routine laboratory studies performed at 2-week intervals revealed no toxic effects on the liver, blood or kidneys in any patient.

In the third study, an additional 143 patients, including 87 chronic schizophrenics, 31 acute psychotics and 25 psychoneurotics, were treated with chlordiazepoxide for from 12 to 20 weeks and the patients followed up to 8 months. Using

the same criteria for evaluation as in the blind study, varying degrees of improvement were shown in 65 or 74.7% of the schizophrenics, 11 showing no change, and 11 becoming worse; in 17 or 54.8% of the acute psychotics, 5 without change, and 9 worse. In 7 of the 11 patients with anxiety reactions the response observed permitted them to enter into psychotherapy. A marked response was noted in 3 of 6 obsessive-compulsives and a good response in 3 of 6 patients suffering from neurotic depression. In the latter 3 patients a great deal of anxiety and agitation was coupled with depression, while the 3 who did not respond did not initially demonstrate a great deal of tension and anxiety.

Two patients with psychophysiologic gastrointestinal disturbances became asymptomatic after 1 and 5 weeks of therapy respectively, and have remained asymptomatic for 5 and 8 months following its discontinuation. At doses ranging from 250 mg. to 400 mg., considerably higher than those used by earlier investigators, the side effects observed were: ataxia, 9, extrapyramidal stimulation, 7, hypermotor activity, 6; and ataxia and extrapyramidal symptoms, 3. When the dose was cut in half the hypermotor activity decreased in 72 hours in all cases.

Chlordiazepoxide was found to be an effective agent for the relief of anxiety and tension with an associated improvement in social behavior. Patients entered into treatment and ward activities more readily and in most cases were more accessible to therapy.

PRELIMINARY REPORTS

A PRELIMINARY REPORT ON THE USE OF STELAZINE AND PARNATE IN CHRONIC REGRESSED AND WITHDRAWN PATIENTS

HARBHAJAN SINGH, M.D., AND RICHARD M. FREE, M.D.¹

In order to ascertain the value of using energizers in treating chronic schizophrenic patients, various studies have been conducted but the results have been somewhat contradictory and inconclusive.

The use of new potent phenothiazines, Stelazine (trifluoperazine) and Prolixin (fluphenazine) in treating regressed and apathetic chronic schizophrenic patients has been somewhat promising.

The aim of this study was to ascertain the effects of one of the most potent antipsychotic tranquilizers (Stelazine) and a potent psychic energizer (Parnate)² in treating chronic withdrawn apathetic patients. The subjects in this study were 25 (12 males and 13 females) withdrawn, apathetic, regressed, chronic patients selected on the basis of having been treated in the past with various tranquilizers, including Stelazine, but having shown no improvement, whatsoever. Their immediate environment, ward placement and participation in hospital activities were kept as nearly the same during the study as before. Each patient was kept off all medications for at least one month before starting the study. By this manner of selection, it was hoped that the patients would act as their own controls. This preliminary study lasted for 6 weeks.

Patients' ages ranged from 28 to 75 years with a mean age of 50.1 years. They had been hospitalized continuously from 2 months to 35 years with an average hospitalization period of 12.9 years. Their official diagnoses varied as follows:

Schizophrenia, all types	14
Manic-depressive Depressed	3
Manic-depressive Manic	1

Mental Deficiency with Psychosis	3
Mental Deficiency with Behavioral Reaction	1
C.B.S. with Huntington's Chorea	1
C.B.S. with Alcoholic Deterioration	1
Psychoneurotic Reaction, Depression	1

PROCEDURE

All patients were started, simultaneously, on Stelazine (2 mg. b.i.d. or t.i.d.) and Parnate (10 mg. t.i.d.). Weekly dosage adjustment of only one drug was attempted at a time, first with Stelazine until optimum dosage, or a dose of 5 mg. b.i.d. was reached. After this, adjustment of Parnate was tried up to optimum level or maximum dose of 20 mg. q.i.d. All patients were told that they were going to be treated with a new drug which might help them. Laboratory studies consisted of weekly estimation of C.B.C., sedimentation rate, Alkaline phosphatase, and urinalysis. Blood pressures were recorded twice weekly except as otherwise indicated.

Evaluations were made weekly. Patients were rated as "much improved," "improved," "same," and "worse" depending on collective agreement of the doctor, nurse, and patient.

The points stressed in rating were: lessening of psychomotor retardation, more socialization, manageability, display of affect and interest, and decrease or disappearance of hallucinations and delusions.

Eight of the 25 patients had to be taken off the study because of severe hypotensive reaction (4), increase in Alkaline phosphatase (3), and acute psychotic excitement (1).

At the end of 6 weeks the final ratings were as follows:

Much improved	4	23.5%
Improved	9	52.9%
Same	2	11.7%
Worse	2	11.7%

¹ Chief of Admission & Intensive Area & Director of Education & Research, respectively, Mental Health Institute, Independence, Iowa.

² Trifluoperazine & S.K.F. 385 (a new mono oxidase inhibitor) supplied by S.K.F. Laboratories.

Treatment with Stelazine and Parnate seems to have been helpful in all diagnostic categories tried in this study. All of them, however, had common denominators: chronicity and withdrawal. In the "much improved" category there were 2 schizophrenics, 1 mental defective with psychotic reaction, and 1 manic-depressive manic. In the "improved" category there were 5 schizophrenics, 2 manic-depressive depressed, 2 mental defectives with psychosis. In the "same" category both were schizophrenic patients, while the "worse" category had 1 schizophrenic patient and 1 C.B.S. with Huntington's Chorea.

Mild side effects noted included agitation, insomnia, akathisia, drowsiness, difficult micturition and hypotension.

SUMMARY

The combination of a very potent tranquilizer and an energizer was tried on 25 chronic regressed, withdrawn, patients with various diagnoses. Eight of the patients had to be dropped from the study because of complications. The results of the present pilot study are promising; however, the above-mentioned combination of drugs requires further trials and research before more definitive conclusions can be reached.

HISTORICAL NOTES

GEORG ERNST STAHL (1660-1734)

ERNEST HARMS, PH.D.¹

Like Paracelsus, Georg Ernst Stahl is better known for what his contemporaries and later medical writers said against him than for what he himself represented. However, he was undoubtedly one of the most influential medical theorists of his time, and as is usual, he was attacked as an enemy of the point of view of his attacker. To the materialist of his day he was a pietist, and to the spiritualist he was a materialist. Actually he was neither. He was a most radical realist with an amazing differential sensitivity which placed him on a new, higher level between the two major camps. True, he was difficult to understand. He wrote a baroque Latin mingled with contemporary German expressions. If we did not have the admirable translation of his *Theoria Medica Vera* by the psychiatrist Karl Wilhelm Ideler, in the beautiful and lucid German of a Romantic essayist, we would be hopelessly lost in trying to understand him. In this remarkable Germanization, the brilliance of Stahl's basic deductions becomes wonderfully clear.

As Paracelsus once stood up against the alchemistic metaphysicists and tried to clear the air for the formulation of natural scientific laws, so Stahl stood up against the "man a machine" mechanistic materialism of his age. He applied his rationalistic thinking to the differentiation between matter and organism: A living organism cannot be only mechanically functioning matter; the body begins to disintegrate at the moment of death; life must be an addition to matter. This additional element Stahl designates as "*animus*," which, however, is not a deistic spiritual element but a "*motus*," as he calls it in his Latin, a movement, a dynamic element—which was, in the following century, designated as "*psyche*." The Ger-

man medical historian Kirchoff believed that it was identical with Hippocrates' "*physis*." The placing of the human psyche "between heaven (not spiritual) and earth (not a physiological element)," as he himself expresses it, is the great achievement of Stahl. Despite the claims that the psychoanalytical concepts of this century were the first to have developed the dynamic aspect of psychology, its real discoverer and first representative was G. E. Stahl. Stahl's starting point was the need for a clear teleological concept as the basis of human existence; the final result was what, in its most modern form, C. G. Jung has formulated as the human psyche as a closed unit of a dynamic system. It was especially this clear and systematic thinking that accounts for Stahl's great influence, which during his time extended all over Europe.

To be historically objective one must hand to Paracelsus the palm for having initiated psychotherapy by his demand that the insane be viewed not as persons possessed by the devil and punished by God, but simply as sick human individuals. But Stahl's influence on the development of psychiatry was no less great, since he was the first to demand concrete psychological treatment. Although hardly a practitioner in the care of the insane, one of his most important writings, his *De Animi Morbis* (1708), was devoted to psychiatric treatment methods. He clearly distinguished between mental diseases resulting from actual bad behavior and those physiologically conditioned, among which delirium was for him the most characteristic. He also clearly differentiated between psychosomatic and somato-psychological influences. The latter, normal functions, he described in great detail in his more scientific version of the old concept of the four temperaments. He saw *animus* functions as influencing the body psychosomatically in a dual way, by contracting and extend-

¹ Editor of *The Nervous Child*, 30 West 58th St., New York 19, N. Y.

ing—a concept that attained its classical form in Goethe's "systole and diastole." Abnormal functioning of the *animus* is the major cause of all insanity. Kirchoff correctly pointed out that the first clear psychiatric differentiation—Langermann's diopathic and sympathetic mental ailment—goes back to this concept of Stahl's. There can be no doubt that the great psychiatrists of the

past century—Reil, Heinroth, and Griesinger—were profoundly influenced by Stahl, who was their major source of thought. When the history of psychiatry matures to become an objective survey and not merely the history of this or that school of psychiatric thought, it will have to recognize Georg Ernst Stahl as one of the four great fathers of psychiatry.

POEMS

PERFECTION AND RETREAT

by EARL D. BOND, M.D.

A Gentleman

A gentleman, the soul of honor
Preferred the rose
Because of its thorns
Preferred to punish himself
And incidentally others
Pleasures for him
Were three parts pain
A knight, he fought for truth
Rather than for men and women
Fearful, he did brave things
Weak, he became strong
To endure, to grasp, to suffer

Never was he satisfied
Until too soon
He broke his lance
Against astonished Death
And ended gratefully
A dutiful existence

"Excelsior"

He knew frustration all his life
And while he raged at compromise
He had to deal with men less wise
And could not find a perfect wife

And when he tried to write a book
He could not get beyond page one
So much there was still to be done
A point he could not overlook

Poor boy, he thought that he was right
To climb a mountain late at night
A snowdrift cooled the fevered quest
Of one who gave up good for best

The Next Step

Let the dull crowd climb
I remain
In my own perfection
In my own province
Where I make the rules
Reject the burden
Take the dream
Not unhappy as I sleep

Across a gulf
Hands stretch out
I almost pity them
From my nest
Beneath the heart

Lover and loved
Subject and object
In the clear pool
I see myself
Safe from
The next step

Perfectionist

I follow a star that is
Above the heads of men
Athirst I stoop to drink
And the water recedes
My lips never touch completion
Always Alpha, Alpha, Alpha
Never Omega period finis end
Too much becomes too little
Is there some fault
That makes perfection perfect?

Infant-Adult

Mother and Wife and Nurse
 Three in one
 She feeds me
 Wheels me
 With other babies
 On the Boardwalk
 She is my slave
 "I toil not, neither do I spin"
 Ruler of a tiny realm
 Master of Time
 Secure in my dependence
 Powerful in my weakness
 To some extent, I live

Double Denial

"Buy me golden shoes, Mother,
 And a servant to make them shine."
 "You shall have what you choose, My Son,
 Because you are wholly mine."

 "Give me your house and lands, Mother,
 Give me a coach and four."
 "I place them in your hands, My Son,
 I wish I could give more."

 "Tomorrow I must die, My Son,
 Comfort me while I live."
 "Why should I answer your cry, Mother,
 When you have nought to give."

Without Love

Love's substitute, ambition grew
 He worked all day and grudged his
 sleep
 At times he worked the whole night
 through
 Such toil as made the angels weep

 And when he reached his pinnacle
 The goal to which his labor led
 He faced the inadmissible
 And put a bullet through his head

Queen

The Queen of beauty
 Withdrew to her castle
 On a lonely hill
 Where all winds moaned
 And no children played

 Around the house
 Tiny graves for those children
 Who never were
 No people came
 But many ghosts

 Her disciplined thoughts
 Never strayed
 Beyond the walls
 No sorrow, no grief
 Embedded in the amber
 Of her self sufficiency

COMMENTS

RANDOM REFLECTIONS

After a period of a generation or more in psychiatry, one is tempted to interrupt the lively present with "flash-backs" to earlier decades. As a budding medical man the "roaring twenties" fascinated me, —the feverish thirst for new knowledge and a better way of life that usually follows great wars. In the young discipline of psychiatry it took the form of rooting out the evil "id" from man's unconscious. Evil was in-born to our Victorian parents as they looked around at the cruel sweat shops, the slums, and the worshipping of money as though it had personality in its own right. To be sure, doctors in the twenties along with everyone else were making money in the booming market, but it was mostly an adventurous game plus a spirit—of general rebellion against the old status quo with its sticky and over-rigid conformity patterns.

Another "flash-back," to the next decade, sees these same doctors seriously discussing their professional futures through the smoky glasses of the economic depression. Those of us in teaching positions literally had to snatch live bodies from the charity clinics to teach with before the local medical society could declare these people "out of bounds." They could afford to pay \$.25 a visit to their family doctor, so what right had they to be treated free in the tax-supported general hospital! Indeed, the thirst for new knowledge in this decade was peculiarly lacking, or so it seemed, except for the few whose livelihood depended on research along with their teaching.

The favored ones in those days, including doctors, were those on salary. In that bitter day most people were more concerned with holding onto their jobs for bread and butter than with the advancement of knowledge. Visits to veterans hospitals before the period of re-vitalization of the Veterans Administration following World War II were depressing indeed. Many doctors in our public institutions who got their jobs more through "pull" than skill slept at staff conferences and made little or no contribution

to the advancement of the specialty. It was heart-breaking for the few dedicated career doctors in these organizations. It was in general a dull, contracted constipated era.

Flash-back Number Three!—The post-war mid-forties found doctors pouring out of armed services full of ambition and idealism to practice the kind of comprehensive medicine they had enjoyed in the better Army hospitals and clinics where the sick soldier had the benefit of specialists pooling their knowledge in practically all fields for his benefit. I watched these same doctors as they came home eager to do the same for their civilian patients. It was a joy to feel their enthusiasm and to know that they truly held the practice of good medicine above other considerations, whether that was solo practice in rural areas or some form of group practice in the city.

Flash-back Number Four!—Medical needs of the public had so piled up during the war that every doctor soon found his office swamped with patients. Money seemed of little consequence to the latter. An appointment with their doctor was all that mattered. The doctor had to meet this civilian emergency the best he could. Coronaries as well as money came more readily to doctors than ever before,—big cars, big suburban homes, but with little time to enjoy them or the wives and children who lived in them. Many of these over-worked physicians expressed deep concern over the situation. Not enough doctors were available to help them handle the loads much less do the kind of job they had hoped to do. Many of these able men would have taken full time teaching and research positions had enough medical school openings existed. More and more hospitals were built and fortunately more and more doctors' buildings erected where the practitioner and the specialist could confer and at the same time advance each other's knowledge. The financial situation of the country was such that had there been twice the number of psychiatrists in

private practice their offices too would have been filled with patients apparently willing and able to pay their doctor as well as the mounting costs of hospitalization. This busy period of lush practice enabled both doctor and patient to profit by a wave of comprehensive medical practice never seen before. Contrary to some savants whose opinion I respect, the Money-happy Fifties have not really left the medical profession less of a "profession" and more of a "trade." Doctors have been blamed for a situation they did not create and could not by themselves change. A great depression and a World War left powerful repercussions.

Contemporary 1960's!—No recession is yet in sight but thoughtful doctors are worried about their profession. Can it meet the needs of the future? In spite of doctors' large incomes there are fewer applicants for medical school and fewer "A" students in proportion applying, if we take the country as a whole. All traditional fields of graduate work, I understand, are having recruitment problems. New alluring fields are now competing for the able student, offering prestige as well as earlier financial returns. A few more medical schools are opening, but hardly enough to catch up with our expanding population. Doctors are as busy or busier than ever. As neglected post-war medical needs were met and new insurance plans developed, the public's appetite for more and better medical care resulted. As Ford's higher wages policy enabled workers to buy more automobiles, it also bought more medical care. Higher wages for laborers often carried with them health insurance benefits which pay up to \$10,000 for prolonged illnesses. But woe to the white-collared man today who does not work for such a firm! One prolonged mental or physical illness can take his house and automobile away.

In time this will be remedied we hope by voluntary health insurance, or certainly by some equally efficient as well as economical system of medical care. In the meantime, however, there are and will be for some time ahead a large number of respectable people who cannot afford private medical care and yet do not want to feel they are therefore second class citizens. Doctors cannot alone remedy this situation. They

cannot help with the high cost of hospitalization. While private and public insurance agencies are working out these basic problems, doctors, bankers and hospital administrators could help make this transition period much less catastrophic for this important segment of our citizenry. Nowhere in the private practice of medicine is this so-called two-class society more in evidence than in psychiatry. There are far too few private practitioners of psychiatry in this country as a whole to solve the problem. Many large communities never had a psychiatrist in private practice until after World War II. The practice of psychiatry in the community is young with tender shoulders. Nevertheless, there are some things we might be able to do besides making our prices reasonable, as was again urged on all physicians recently by Dr. Louis M. Orr, Retiring President of the A.M.A. It is not charity from doctors that people want, but some organized resource whereby one can at least see a doctor when he is most in need of one at fees geared to his pocket book.

In this regard there is an interesting experiment in cutting down the waiting list in a child guidance clinic with which I am acquainted. Private psychiatrists might do some similar experimenting along these lines. This clinic decided to open a Thursday afternoon emergency psychiatric examination clinic for parents and their problem children. After an intake interview by a skilled social worker, both child and parents were seen first together then separately for the first hour. A conference was then held by the psychiatric resident and social worker with a senior staff person as consultant* and recommendations agreed upon; then a final session with the parents with or without the child present, and the examination was dictated for the record.

This afternoon clinic cut the traditional treatment waiting list of the clinic to less than half. It did more than that. The clinic was able to refer half of these cases to other agencies in the community for help, with the clinic staff offering "stand by" consultation service when needed. The families so referred felt satisfied with such an examination and were reported to have cooperated well with the other agencies to whom they were referred,—such as visiting

teachers, family welfare agencies, pediatricians, *etc.* In one month three adolescents with incipient schizophrenia were referred to hospitals, two having full health insurance coverage through their fathers' firms for private hospital treatment. Incidentally they were previously unaware of this kind of coverage.

Today when some psychiatrists are deliberately taking extra time off to cut income, adaptation of this or some other plan to their own way of working could render crucial help to many at the time when an expert appraisal of their problems is most needed. Needless to say the referring family physician is always grateful for such examination and recommendations. With the community paying the salary of the social workers, fees taking care of the overhead,

and each psychiatrist volunteering two hours of time each week, I see no reason why such an examination and referral service by psychiatrists in private practice could not be put into operation. Unfortunately creative ideas and good motivation often go to waste for lack of proper machinery to express them. Here is where experts in psychology, social work and community planning could help us.

Let us not wait for others with less training in the social side of medicine to act for us as they might do all too quickly. Where the need is made evident may we not assume that psychiatrists in private practice will be found willing to sacrifice a lucrative afternoon in their offices to give clinic service such as outlined?

S. S. A.

INTOLERANCE

The intolerance of old age is matched by the intolerance of youth. The cure for the former is the memory of one's past. The only cure for the latter is contained in the sad experiences which no generation can escape.

GENETIC FACTORS IN SCHIZOPHRENIA

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: The good article in the May issue, "Genetic Factors in Schizophrenia," by Dr. Ian Gregory, indicates that, although there is suggestive evidence that heredity may play some role in the etiology of this disease, the studies published up to the present fail to support the hypotheses advanced as to a specific genetic mechanism. These studies have all dealt only with overt schizophrenia and treated it as a single condition rather than the group of diseases Bleuler hypothesized may exist. As a partial antidote to the pessimism which this invalidation of previous work may engender, I wish to note an alternative approach which has proved more rewarding in the study of other human diseases. (I have drawn heavily from the ideas of Neel, J. V., expressed in *Am. J. Hum. Genet.* 7: 1-14, 1955, and in *Medicine* 26: 115-153, 1947.)

In a number of diseases, a variation from the normal so mild as not to be called illness has proved in the study of pedigrees to be rather easily fitted into the small whole number ratios of classical genetics, while the morbid condition which was an exaggeration of the minor variation appeared in a distribution which was genetically meaningless. Using gout as one of various possible examples, with elevated blood uric acid as the minor variation, elevation appeared in the parents, siblings, and children of individuals with elevations in numbers approximating the 1:1 ratio which suggests a single dominant gene almost completely penetrant. Appearance of gout in these families was sporadic, meaning that

if overt disease had been the criterion studied, the genetics of this disease would be no better understood than that of schizophrenia.

"Schizoidness" or various partial components of the schizoid personality may well be more consistent with gene behavior than schizophrenia. The problems immediately arise as to which traits are exclusively schizoid, as to where to draw the line between abnormality and normality for any component trait, and as to whether these traits may be determined by environment. It seems to me unnecessary, even undesirable, to decide which component traits on which to concentrate prior to the collection of pedigree data. Possibly it could be found that some indices behave as if inherited, others as if learned (as, for example, almost always present if present in mother but seldom present if present in father), while still other indices would lack predictability. Among indices which could be tested are various facets of mental status, developmental history, psychological test items, and physiologic measurements. Discovery of even one index which behaves like a gene would be a step toward an etiologic classification of mental illness from the present descriptive classification. As an index of susceptibility, it would be a help to researchers attempting to determine what environmental factors promote or hinder development of overt schizophrenia(s).

Willard S. Schwartz, Jr., M.D.,
Resident, Western Psychiatric
Institute and Clinic,
Pittsburgh, Pa.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Thank you for the opportunity to comment on the letter from Doctor Schwartz

concerning my recently published analysis of genetic factors in schizophrenia.

It is true that certain disorders (such as gout) may be irregularly manifested among

a larger group of individuals having a metabolic anomaly attributable to single gene inheritance. It is not quite correct, however, to state that all genetic studies on schizophrenia have hitherto dealt only with overt schizophrenia and ignored the possible transmission of more widespread latent "schizoid" tendencies.

Kallmann has postulated that the potentiality for overt schizophrenia is inherited as a simple autosomal recessive unit characteristic with incomplete penetrance and expressivity (determined by a genetically non-specific constitutional defense mechanism). He also speculates that both homozygotes failing to manifest overt schizophrenia and individuals heterozygous for the pathological gene (who must number 20 to 25% of the general population to conform with this theory) may have either a schizoid or normal type of personality, and that the principal genetic derivation of involutional psychosis is from the schizoid personality.

There are many reasons why the majority of human geneticists are not prepared to accept simple formulations of this nature concerning the possible contributions of heredity to the etiology of most common psychiatric syndromes such as the schizophrenias. Clinical psychiatric diagnoses, for example, are not sufficiently precise—both

American and British studies indicating about 30% disagreement between major diagnostic categories used to describe the same patients in different but nearby hospitals.

The complex data that have accumulated appear to preclude any single gene hypothesis of causation for either (a) all varieties of overt schizophrenia or (b) any larger category (schizoid or other), a certain proportion of which included all varieties of overt schizophrenia. Three alternative hypotheses (that are *not* mutually exclusive) were considered briefly in my article: 1. Predominantly environmental causation, 2. Genetic heterogeneity, 3. Polygenic inheritance.

The improbability of a single gene basis for the whole of "schizophrenia" (or of "schizoid personality") does not exclude the possibility that genetic factors may be important or even essential determinants of at least some varieties of schizophrenia. The current lack of certain knowledge should stimulate the search for more objective diagnostic criteria, and their application in extensive family investigations.

Ian Gregory, M.D.,
Department of Psychiatry,
University of Minnesota.

URINARY EXCRETIONS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: I read with great interest the paper of F. Christine Brown, Ph.D., J. B. White, Jr., B.S., and J. K. Kennedy, M.D. about the "Urinary Excretion of Tryptophan Metabolites by Schizophrenic Individuals."

In 1927 and 1928, E. Scheiner, M.D. published two papers, entitled "Reazione nera (Buscaino), reazione dell' uroscina, reazione di Millon nell' urina di amenti e dementi precoci" and "La Reazione di Millon nell' urina delle psichosi tossiche," in which he stated that the urine of schizophrenics has an increased content of aro-

matic amines. My superior at that time, Prof. Wagner-Jauregg asked me to check Dr. Scheiner's findings and I obtained the same results as Dr. Brown, J. B. White, and Kennedy with the methods available at that time, namely that there is no increased urinary excretion of aromatic amines in schizophrenia. My findings were published in the *Jahrb. f. Psych. & Neur.*, Vol. 47, P.1, in an article entitled "Ueber die von Scheiner angegebenen vier Harnuntersuchungsmethoden."

Edith Klemperer, M.D.,
New York, N. Y.

DYNAMIC ORIENTATION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : Dr. Mark Stewart's letter about posts requiring a "Dynamic Orientation" from applicants says something that long needed saying. But this is not the only unfair practice that our Association tolerates. For many years appointments to academic posts in psychiatry, psychology, and social work have been made, openly or tacitly, only to those who have completed a personal analysis. Karl Jaspers¹ drew attention to this violation of academic freedom. Needless to say, someone who dissented from the main doctrines of psychoanalysis would not be regarded as successfully analysed.

Furthermore, scepticism about the value

of psychotherapy is regarded by some as disloyal, and its expression has been seriously proposed as punishable by our Association. This is not the attitude of mature men, sure of the basis of their convictions. Criticism of physical methods of treatment by contrast is acceptable and even praiseworthy.

What a stroke of salesmanship was the appropriation of this word dynamic! Freud's deterministic system, with the timeless unconscious and the repetition compulsion, should much more appropriately be called psychostatics. Dynamic seems a more suitable adjective for psychiatrists who emphasise the individual's creative possibilities, and his power to synthesise new ways of living, unpredictable from his past.

Elliott Emanuel, D.P.M.,
Dorval, Que., Canada

CARRYING ON

Man continues to live because he is a living creature, not because reason convinces him of the certainty or probability of future satisfactions and achievements. He is instinct with activities that carry him on. Individuals here and there cave in, and most individuals sag, withdraw and seek refuge at this and that point. But man as man still has the dumb pluck of the animal. He has endurance, hope, curiosity, eagerness, love of action. These traits belong to him by structure, not by taking thought.

—JOHN DEWEY

INTELLIGENCE

It is customary among a certain school of sociologists to minimise the importance of intelligence, and to attribute all great events to large impersonal causes. I believe this to be an entire delusion. I believe that if a hundred of the men of the seventeenth century had been killed in infancy, the modern world would not exist. And of these hundred, Galileo is the chief.

—BERTRAND RUSSELL

NEWS AND NOTES

PAPERS OF PROFESSOR C. K. CLARKE.—Through the generosity of his daughter, Miss Emma de V. Clarke, Dr. Clarke's papers have been presented to the Department of Psychiatry of the University of Toronto, where this valuable historical material will be available for study.

In accepting Miss Clarke's gift on behalf of the Department, Professor Aldwyn Stokes spoke in appreciation of Dr. Clarke's great contribution which is becoming increasingly recognized.

Dr. Clarke was the first professor of psychiatry in the University of Toronto (1906-1924). He had also served as Dean of the Medical Faculty, and during World War I had been head of the Department of Psychology and superintendent of the Toronto General Hospital. He was the first director of the Canadian National Committee for Mental Hygiene and held that position until his death in 1924. He had been superintendent of Ontario Mental Hospitals both at Kingston and Toronto. He established the first outpatient psychiatric clinic for children in Canada. He was the first Canadian to serve on the editorial board of the *American Journal of Psychiatry*.

Considering his pioneering work and his constructive leadership throughout his long professional life, C. K. Clarke may be ranked as the preeminent representative of the mental health field that Canada has produced to date.

THE NEW JERSEY NEURO-PSYCHIATRIC INSTITUTE.—The 8th annual Psychiatric Institute will be held at Princeton, N. J., Sept. 14, 1960, beginning at 9 a.m. The theme will be Psychiatry in Foreign Lands. President of the APA, Robert H. Felix will preside.

The assignments are: France, Holland, Belgium—Dr. Barton; Russia—Dr. Lebesch; Pakistan, Thailand, Indonesia—Dr. Morse; Japan—Dr. Balser.

At the dinner meeting at 7 p.m. at the Princeton Inn, the third annual Nolan D. C. Lewis Award will be presented.

AMERICAN ACADEMY OF PSYCHOTHERAPISTS.—The fifth annual conference of the Academy will be held in Cleveland, Ohio, on October 15 and 16, 1960, at the Hotel Carter. The title for this meeting will be "Psychotherapy—Healing or Growth." The format will be based on a phenomenological approach rather than according to schools of psychotherapy. There will be at least four panelists. The discussion is to be impromptu and no paper is to be read. It will be chaired by Dr. O. Spurgeon English. The attendance will meet in small discussion groups and formulate questions for the panel. For further information write to Dr. Bill J. Barkley, Chairman, 1856 Coventry Road, Cleveland Heights 18, Ohio.

O. T. NEWSLETTER.—This publication is available free of charge from the Editor, Alan H. McLean, M.D., I. B. M. Corp., 590 Madison Ave., N. Y. 22, N. Y. and not from the Mental Health Materials Center as stated in the July issue. The publication *Troubled People on the Job* is available at .50c from the Center, 104 E. 25, N. Y. 10, N. Y.

DOCTORATE IN NURSING SCIENCE.—Dean Marie Farrell of the Boston University School of Nursing announces that a Doctor of Nursing Science degree, the first doctorate in the country which specifically identified nursing in the degree title, has been established at the Boston University School of Nursing.

The first doctoral offering is in psychiatric nursing, with programs in other clinical areas to be instituted in the next two to four years.

Previously, the highest level of training offered at the School was the Certificate of Advanced Professional Specialization, consisting of a minimum of 30 semester hours of advanced study beyond the master's degree. The new degree program calls for a minimum of 60 semester hours' credit in advanced, directed study, plus a doctoral dissertation.

Overall, the objective of the advanced psychiatric nursing program will be to develop further the nurse's role, to include well-defined psychotherapeutic responsibilities which she undertakes in collaboration with the psychiatrist. Extension of this nurse-therapist's role into research, teaching, administration and consultation will be further utilization of the knowledge gained in her doctoral study.

Generous financial support for the establishment of this program has been granted to the University by the National Institute of Mental Health.

KAREN HORNEY ANNIVERSARY.—To commemorate the 75th anniversary of the birth of Karen Horney, the Association for the Advancement of Psychoanalysis is sponsoring a symposium on "Alienation and the Search for Identity," November 5 and 6, 1960 in the Carnegie Endowment International Center in New York City. The main sub-topics will be: "Alienation and the Self," "Alienation and Culture," and "Alienation and Therapy." Some 20 speakers will participate.

RESEARCH FOUNDATION OF THE NATIONAL ASSOCIATION FOR MENTAL HEALTH.—This new unit of the National Association will allocate grants for projects and programs concerned with the causes, prevention and treatment of mental illnesses. It will also provide fellowships for medical students interested in research on mental illness.

The foundation will assume the functions of the research department of the National Association for Mental Health, which has been functioning since early 1959, and which has to date allocated \$208,500 in research grants.

President of the research foundation is Dr. Harold Elley of Wilmington (Del.), formerly chief of research of I. E. duPont de Nemours Company. Its director is Dr. William Malamud, who also serves as director of Professional Services of the National Association for Mental Health. Dr. Malamud is also director of the Schizophrenia Research Committee of the Supreme Council 33° A. A. Scottish Rite, Northern Masonic Jurisdiction. The Scottish

Rite grants are disbursed through the National Association for Mental Health.

THE AMERICAN PSYCHOSOMATIC SOCIETY.—The Society will hold its 18th annual meeting at Chalfonte-Haddon Hall in Atlantic City, April 28, 29, and 30, 1961.

The Program Committee would like to receive titles and abstracts of papers (9 copies) for consideration. Time allotted : 20 minutes. The deadline for abstracts (not more than 2 typewritten pages) is December 1, 1960.

Abstracts should be addressed to the Chairman, Morton F. Reiser, M.D., at 265 Nassau Road, Roosevelt, New York.

ANNALS OF THE NEW YORK ACADEMY OF SCIENCES.—This publication, dated April 22, 1960, is given over to the topic "The Organization of Psychiatric Care and Psychiatric Research in the Union of Soviet Socialist Republics" by Dr. Nathan S. Kline of Columbia University and Rockland State Hospital.

Dr. Kline treats the subject under the headings of Organization of Psychiatric Care, Organization of Psychiatric Research, and Generalizations from Psychiatry to Society, followed by five appendices : Psychiatry in Czechoslovakia, Research Activities in Soviet Institutes, Neuropsychiatric Facilities in the U.S.S.R., Research Plan of the Academy* of Medical Sciences and Resolution on Academician I. P. Pavlov.

INTERNATIONAL SYMPOSIUM, EXTRAPYRAMIDAL SYSTEM AND NEUROLEPTICS.—This symposium, organized by the Department of Psychiatry, University of Montreal, will be held at the University, November 17, 18 and 19, 1960. The symposium will be introduced by J. Delay and P. Deniker (Paris), and eminent speakers from Germany, France, England, Switzerland, Belgium, the United States and Canada will participate.

The main subjects for discussion are : 1. Anatomy and Physiopathology, 2. Pharmacology, 3. Parkinson's Disease, 4. Extraparamidal Syndromes and Clinical Psychiatry, and 5. Special Topics.

For information write to Jean-Marc Bordeleau, M.D., Secretary of the Symposium, Department of Psychiatry, University of Montreal.

DR. ROBERT ROESSLER TO HEAD WISCONSIN PSYCHIATRIC INSTITUTE.—The appointment of Professor Robert Roessler, Chairman of the Department of Psychiatry, as Director of the Wisconsin Psychiatric Institute was recently announced by the Regents of the University of Wisconsin. The dual appointment serves as a means of combin-

ing in effective teamwork Wisconsin's clinical, educational and research resources in the field of Mental Health.

Dr. Roessler has been Asst. Prof. of Neuropsychiatry since 1950. He received the B.S. in Philosophy from the University in 1942 and a M.D. from Columbia in 1945. He became Acting Chairman of the Department of Psychiatry in 1956 and permanent Chairman in 1957. Under his leadership, an integrated residency program with the Department of Public Welfare has been developed.

EFFECT OF EDUCATION

Great minds are pre-eminently good or bad, and education makes them better or worse.

—OSLER

GOVERNMENT

Popular government or democracy is going to fail if left solely to the official class. There must be a volunteer class, of strong, capable men offering their services and interesting themselves actively in the affairs of the government.

—WILLIAM H. WELCH

BOOK REVIEWS

HUMAN POTENTIALITIES. By *Gardner Murphy*.
(New York : Basic Books, 1958, pp. 340.
\$6.00.)

This book poses the central problems of our time, and promises answers. It asks the question "Where is mankind headed?" with the clear implication that the reader will be handed a time table, a map, and a set of directions. "One of America's foremost psychologists," the jacket proclaims, "dramatically shows us how we can, by our own free choices, control not only our destinies, but those of countless generations to come."

Unfortunately, the promised potentialities remain unfulfilled. It is doubtful whether we, or the "countless generations to come," can derive more from this volume than an interesting statement of Gardner Murphy's views on the nature of human evolution. It is his central premise that human nature has changed and is changing. Should we become aware of the nature of ongoing changes, and of our role in determining them, we may control them for the better. Presumably the book is intended to aid in this process. And since it is mainly the scientist who would provide the awareness and determine the improvements, it is to him that the book is implicitly addressed.

Man, at present, is a cumulative composite of 3 "human natures." The first is close to that of our simian ancestors. It derives satisfaction from all manner of activity, experience, and learning. But soon certain experiences and activities come to be reinforced, and the process of "canalization" sets in, which creates the "second human nature." Here man becomes progressively molded along lines determined by particular cultures, and these molds harden. Despite the pressures with which cultures stifle inventiveness and seek to perpetuate their preferred systems of habits and percepts, a quest for understanding, an insatiable curiosity arise. This is the "third human nature."

In the process of exploring and changing the world, man himself becomes changed. There is no boundary between man and his environment (an adaptation of Lewin's "life space"), the two are inextricably linked and evolve together. We can therefore shape ourselves by shaping the world, and *vice versa*. This is the argument. Nothing less, and very little more. This disappointingly simple and relatively superficial argument is stated in language which frequently glows, and some-

times sparkles. Describing mankind's present dilemma, for instance, Murphy remarks that "there appears to be no escape for any of us but to hide in the hills in the hope that radioactive fallout will somehow not drift into our caves." In his chapter on "rigidity" he tells us that "there is such a thing as being battered down, either dramatically or just quietly and steadily year by year, until one no longer looks up." In a chapter on creative phases of history, we read : "We must demand always that proof be given that the impossible is truly impossible." Children should be encouraged to develop their creative potential ; one must study "the ways in which the fires of infancy can be gently transferred to the new furnaces of high creativity." He describes this process elsewhere as "first support, a hand to hold ; then a few steps alone ; then a race against time to see how much a short life can yield."

One cannot but experience delight at the exquisitely modulated phrases, the unexpectedly appropriate words scattered throughout the book. Our First Human Nature wallows in this verbal confectionery. Our Third Human Nature, however, cannot but wonder whether some of these refinements might not have their origin, like the erotic extravagances of certain Oriental potentates, in the need to deviate from an excessively repeated pattern.

Indeed, as we read through the book, we are assailed time and again with a feeling of *déjà vu* which turns out to have a sound basis in external reality. Murphy experiences the same thoughts over and over, and repeats them mostly with minor variations. It is an uncanny experience to read page after page of iterations and reiterations, only to meet the now familiar ideas again, in a slightly different context, a few chapters later. The exposition of the 3 human natures, for example, consists of pages of synonymous descriptions. Ideas such as that by changing civilization we change human nature ; that man is one with his culture and with the "cosmos" ; that we cannot extrapolate into the future because of emergents, and that we need more research (e.g., about eugenics), appear again and again. There are many cross-references, some of which seem to hold out the prospect of analyses that are never carried out, or pronounce as answered, questions that have hardly been posed.

One frequently gains the impression that

the author regards a problem as solved merely because he has mentioned it, or assumes that a set of assertions constitutes an argument. He describes "cultural lag" for instance, and tells us that he has provided us with a clue for its explanation. He dismisses a major portion of contemporary social science—the concern with the development of organization man, suburbia, etc.—with a passing reference to impulses like the need to make discoveries. He resolves the issue of free will in 4 or 5 pages. He disposes of rationalism by calling it "dogmatic." In many places, *Human Potentialities* contains assertions for which no factual or logical support is offered.

Occasionally empirical statements are made which are possibly subject to question. We are told that "mutations are constantly going on (probably one mutation for about 5 new births)." At another point we are told that young people could not be creative in times of depression or during post-war periods because "there was no great idea on whose wing they could fly." What of the bulk of American and European literature which flourished in precisely such times? Possibly we have misunderstood Murphy's point, since some of the most impressive passages in the book are discussions of literature, music, and art—especially art. The author shows a familiarity with and a love for art which would do a professional critic or art historian justice.

It is not a function of a reviewer to take issue with a writer's position on substantive matters, but it may be legitimate to make such a position explicit. We note that Murphy introduces a mystical element into his book. He talks about man having "affinities," "resonance" or "isomorphism" with the universe, of man's structural relatedness to the cosmos. He endorses parapsychology, which he regards as supported by overwhelming evidence. He also takes a position in favor of eugenics. On the other hand, he has little to say about social improvements, about problems of inequality, poverty, oppression or prejudice. He does not talk about economic or social relationships. He makes no reference to the role of low status or economic deprivation in stunting human potentialities. Murphy's feeling seems to be that our hope rests in the scientist, and not in the revolutionary. He sees understanding rather than social reform, as the key to the future. Some of us may quarrel with this emphasis, but it is certainly legitimate. By the same token, however, we need not accept Murphy's implied contention that a disagreement with his position on, say, parapsychology, denotes narrowmindedness, in-

tolerance, fear, or obstruction of progress. Merely because an idea falls outside the mainstream of science does not make it progressive. It may be, of course, but on the basis of past experience the probabilities are against it.

This reviewer found chapters on "rigidity" and "creativity in our era" thought-provoking and impressive. He was less happy with a section on "biological changes in man" in which the author discusses eugenics (favorably), or a chapter in which he examines moral implications in science. For "least liked" chapter, this reviewer would nominate one which contains speculations about alternatives open to the world among possible "orders" of society. The selection of the alternatives presented seemed to be somewhat arbitrary.

It is unfortunately not possible, in due conscience, to end this review by recommending *Human Potentialities* as bedside reading, as a professional reference book, or as a volume with therapeutic properties. It is a highly original and relatively systematic set of ideas about human nature and its evolution. Those who are interested in this sort of thing should find it rewarding.

THE LIFE AND TIMES OF SIR CHARLES HASTINGS. By William H. McMenemy. (Edinburgh: E. & S. Livingstone; Baltimore: Williams & Wilkins, 1959, pp. 516. \$10.00.)

Study of the history of medical organizations often reveals the fact that they owe their existence and development to the enthusiasm of one man. The British Medical Association is no exception to this rule, for it owes its existence to an English physician of great ability and charm, who saw the need for medical unity and had the foresight and energy to put his vision to practical use.

Sir Charles Hastings was born in 1794, apprenticed to two apothecaries and appointed house surgeon to the hospital of Worcester, England, while still a teenager. As soon as circumstances permitted, he resigned his post to study in Edinburgh from which he emerged with an M.D. in 1818. He was determined to be the foremost physician in Worcestershire, and lived to see his ambition fulfilled. He was an acknowledged authority on diseases of the chest at the age of 26, and somewhat later, because of his desire to spread medical information, turned his thoughts to journalism. In 1828 he started a journal known as the *Midland Medical and Surgical Reporter*. Un-

fortunately, after a period of success, the journal folded up as a result of the business failure of its publisher, Mr. Tymbs.

Nothing daunted, Hastings promptly formed an association known as the Provincial Medical and Surgical Association, mainly to sponsor the medical journal he edited. Thanks to his careful planning, the association thrived from the start and Hastings became one of the first two secretaries, serving in this capacity for many years, and subsequently being appointed the permanent president or chairman of the council of this association. It is interesting to note that at the second meeting in 1833 when 316 members had already gathered together, the whole progress of medicine and surgery for the year was reviewed by Dr. Barlow in one hour. Incidentally, the first American visitor to an annual meeting was Dr. Sweetser of Boston who was warmly welcomed in 1835.

The present biography of Hastings and his times is aptly named, for McMenemy is concerned not so much with a personal biography as with a story of the interplay of Sir Charles Hastings' ideas and activities, and the problems of the day such as medical reform with the demands of licensing of practitioners and unification of qualifications in England, and the constant running battle between medical practitioners and the Poor Law authorities over the medical care of paupers. The Provincial Association which Hastings founded grew in strength under his wise guidance, while other rival societies founded in London withered away under internal conflict. Hastings constantly kept before him the need to keep together the physicians, surgeons and general practitioners, and gradually wore down the criticisms of Thomas Wakley, the fiery editor of the *Lancet*, who began by castigating the Provincial Association and ended by admiring it.

Yet even Hastings had his blind spots, for when the day came when London wished to join in and the time was ripe for renaming the society the British Medical Association, Hastings first opposed this move. However, when he eventually saw the need for a new name, he was the first to propose it, and the British Medical Association was born in Birmingham in 1855.

There is very little in this book about the private life of Hastings, that is, assuming that his many activities in medical politics and his practice (which included the proprietorship of a lunatic asylum) left him any time for a private life. But his public activities are documented to the last degree, and this book is obviously designed to be the definitive biog-

raphy for many years to come. It is an essential for medical historians, and a near-essential for any student of medical politics. The story carries lessons for organized medicine even today.

Medical Association Journal.

MENTAL SUBNORMALITY, BIOLOGICAL, PSYCHOLOGICAL, AND CULTURAL FACTORS. By Richard L. Masland, Seymour B. Sarason, and Thomas Gladwin. (New York: Basic Books, 1959, pp. 442. \$6.75.)

This book's Introduction states: "The early planning and development of this program was actively sponsored by the ad hoc committee on mental retardation of the National Institute of Neurological Diseases and Blindness and the National Institute of Mental Health as part of their program development activities in this field. The National Association for Retarded Children received additional financial support from the Association for the Aid of Crippled Children, the New York Foundation, the National Institute of Neurological Diseases and Blindness, and the National Institute of Mental Health."

This book is the result of very comprehensive surveys of presently known causative factors in mental subnormality, a term embracing both mental deficiency (organic) and mental retardation (non-organic), so defined by the World Health Organization.

While the book is by no means a primer in the subject of mental deficiency and requires a good deal of prior knowledge to adequately comprehend, it is of great value to those working in the field. Indeed, careful reading might attract to the field those workers of varying professional background who are seeking out projects.

Two separate works comprise the publication, part one being a summary of the biological factors by Richard L. Masland, M.D., a neuropsychiatrist, and part two a discussion of the psychological and cultural factors by Seymour B. Sarason, Ph.D., a psychologist, and Thomas Gladwin, Ph.D., an anthropologist. The distinctly different approaches of the authors, reviewing the works of thousands of individuals in practically all disciplines, emphasize the complicated multiple etiologies in mental deficiency and mental retardation.

Masland presents the prenatal and post-natal organic causes very effectively, indicating what the near-future advances in genetics may be and the public health ap-

proaches to the study and control of environmental agents. He believes some prenatal factor is paramount in the majority of cases and although the biochemical approach is encouraging, the problems in this field should be studied by multidisciplinary groups associated with universities. Masland expresses the psychiatric point of view in that biological, psychological and cultural factors all operate in the entire range of intelligence, and disputes the concept that "organic" brain damage applies only to the severely defective group. Minor mental impairments extend into the normal population and the biological research that Masland has indicated has implications for universal mental health which must be integrated with those derived from work in the psychological and sociocultural fields.

The second section considers in detail the validity, based on theoretical and cultural comparisons, of the concept of mental defect. It reviews in great detail those studies which indicate that the majority of those who are regarded as defective during their educational years prove to be adequate adults, and questions the value of traditional education for that group.

Two chapters deal with the severely defective, pointing out the resemblance of their behavior to psychoses and the need to explain that behavior rationally, instead of dismissing it as due to organic defect. The authors make a strong plea for objective study of, and assistance to, this group, based on approaches devoid of defeatist assumption.

Unfortunately, the style of the second section is of extremely polemic character. There is a "harping" quality about the questions raised concerning education, IQ tests, and cultural influences in mental retardation. The authors, after reviewing considerable research in the matter, conclude that present psychometric tests fail to adequately predict adult problem-saving behavior, do not tap a sufficient variety of intellectual processes, are unreliable, and are strongly weighted in the direction of maintaining middle and upper class social values. Although these points are all relatively true, they do not rule out the use of tests in conjunction with all the other criteria regularly used in diagnosing mental retardation. Such tests came into use long after the concept of mental deficiency. To pick on IQ as though it were to blame for creating a pseudo-problem is quite misleading.

A series of recommendations for theoretical review, research and research centers, as well as personnel recruitment and training, conclude the second section. This book should serve

as a valuable text in medical schools, departments of sociology and psychology, and in schools of education.

ESKIMO. By Edmund Carpenter, Frederick Varley, and Robert Flaherty. (Toronto: University of Toronto Press, 1959. \$4.95.)

The text of this large quarto volume is provided by Professor Edmund Carpenter, of the Department of Anthropology at the University of Toronto, the reproductions of sketches and paintings, by the Canadian artist Frederick Varley, and the carvings, which illustrate many pages of the book by the late Robert Flaherty. The importance of this volume for students of the human mind lies in some rather astonishing facts which Professor Carpenter brings out. These relate to the extraordinary mechanical abilities of the Eskimo. Machines that cannot be repaired by experts are child's play to an Eskimo who may never have seen such a machine before! Airplane engines that defy the trained mechanics are a lark to the Eskimo. Asked to draw a map of their island, a land mass of some 20,000 square miles, two Eskimos who had never previously drawn a line in their lives produced maps so accurate that they differ only in the slightest details from those produced by the aerial cartographers.

Has this remarkable faculty something to do with their constant training and necessity to orient themselves in relation to signs which appear non-existent to the non-Eskimo observer? Is there a genetic factor involved here, or is it a matter of cultural conditioning, or both? Evidently, both. But to what extent is this ability culturally conditioned and to what extent genetically? Here is a nice problem for investigation.

This is a charming and attractive account of Eskimos, anecdotal rather than systematic, and very reasonably priced.

Princeton, N. J.

INDIVIDUUM UND KRANKHEIT. GRUNDZUEGE EINER INDIVIDUAL PATHOLOGIE. (Individual and Disease. Fundamentals of an Individual Pathology). By Friedrich Curtius. (Berlin: Springer Verlag, 1959.)

In his introduction, the author explains that anthropological medicine with its concern about the metaphysical meaning of the individual case and with the establishment of a phenomenological, essentially intuitive appraisal-

al of the personality cannot, despite all its importance, answer questions about the biological constellation of the individual patient. He undertakes to show that "an objective, structural analysis of the individual combination of conditions" can elucidate the individual case. Professor Curtius discusses types and concludes that the types are often too broadly conceived. As they, in the reviewer's opinion, never are "realized," but represent only "ideal" frames, it is little wonder always to be faced with deviations of the individual from "his" type. It can be assumed, though, that in the "typical," as a rule, constitutional factors come to manifestation.

Constitutional factors play a role in pathogenesis, in the premorbid condition, in the individual way of response and in organ dispositions. Not all these factors are exclusively constitutional in every single case: it belongs to the hard task of diagnosing to find out as much as possible about all the factors under consideration. The factors mentioned plus environmental factors cannot but lead to the assumption of the pluricausality in the genesis of every case.

There is, however, not only the pluricausality pathogenesis, in which the individuality of the patient is expressed; it also makes itself noticed in the "shaping," in the formation of his sickness (*Krankheitsgestaltung*). Here Karl Birnbaum's notion of the pathoplastic is used with emphasis.

The author demands that in any adjudgment of disease, justice be done to the "nosological reality instead of dogmatic fiction." The particular consideration of the individual ought to modify the "school" diagnosis through the individual diagnosis. Such considerations are as necessary as they are useful in expert opinions (*Begutachtung*) and in respect to prognosis.

Discussing therapy and the combination of diseases, the author devotes several pages to complications during pregnancy.

The text is constantly enlivened and enriched through case histories. There are 58 illustrations, some of them in color.

This is an unusually solid and important book. The author is the chief of a large medical department in a communal hospital in Luebeck (Germany). He has built up this book on his own clinical experience which he has constantly and critically widened and broadened. He tries to be fair to certain psychological influences, some of which seem to blossom in German medicine nowadays, but his own attitude is clearcut scientific. Not without a certain humor does he make the statement that the notion of unicausality only re-

cently dropped in pathology, reenters the scene in psychosomatics. The author knows as well as any of the modern "Psychiker" (word and quotation marks are the responsibility of the reviewer) that people with a labile autonomous nervous system respond accordingly to conflicts. He regrets the exaggeration of constitutional and hereditary factors as much as the one-sided emphasis on environmental influences.

We are given here the fruit of indefatigable clinical work and—as if it were in an aside—are reminded that "facts" weigh more heavily than "theories."

Despite his clearly formulated attitude the author is open to all possibilities that may grow out of the present crisis of medicine.

This book may well become a classic.

EUGEN KAHN, M.D.,
Houston, Tex.

SIGNIFICANT TRENDS IN MEDICAL RESEARCH.

The Ciba Foundation 10th Anniversary Symposium. Edited by G. E. W. Wolstenholme, M.B., Cecelia O'Connor, B.Sc., and Maeve O'Connor, B.A. (Boston: Little, Brown & Co., 1959, pp. 356, ills. \$9.50.)

This volume exemplifies the great service of the Ciba Foundation and its parent Ciba Limited of Basle to medical education and research. Thirteen international authorities representing the range of contemporary research were invited to present those features of work in their fields which they considered most significant for future trends. Seven of these scientists are Nobel Laureates. Ample discussion followed each presentation.

This three-day symposium held in London was undoubtedly one of the most important of the fifty symposia and colloquia originated by the Ciba Foundation and published by J. & A. Churchill, Ltd. Here we can only indicate the scope of the Symposium by listing the titles of papers and their authors in the order of presentation. They were:

1. Molecular Structure in Relation to Biology and Medicine, by L. Pauling of the California Institute of Technology.
2. Fluorimetric Studies on Pyridine-Nucleotide Enzyme Complexes, by H. Theorell, Nobel Medical Institute, Stockholm.
3. Chemical Basis of Virus Multiplication, by G. Schramm, Max-Planck Institute, Tübingen.
4. Population Dynamics of Body Cells, by Sir Macfarlane Burnet, Walter and Eliza Hall Institute, Melbourne.
5. Genetics and Medicine, by J. Waldenström, Malmö Allmänna Hospital, Malmö.

6. Ten Years of General Neurophysiology, by A. von Muralt, University of Berne.

7. The Nature and Mechanism of Action of Hormones, by F. G. Young, University of Cambridge.

8. Metabolic Problems Involving the Pancreas, Choline, Insulin, and Glucogen, by C. H. Best, Banting and Best Dept. of Medical Research, University of Toronto.

9. Research in Chronic Pulmonary Disease, by D. W. Richards, Columbia University, New York.

10. Malignant Transformation: its Mechanisms and Nature, by A. Haddow, University of London.

11. Research in Clinical Nutrition, by J. F. Brock, University of Cape Town.

12. The Quantitative Approach to Disease—Exemplified by Essential Hypertension, by Sir George Pickering, University of Oxford.

13. Factors Influencing the Substance and Dimension of Medical Research in the United States, by J. A. Sannon, National Institutes of Health, Bethesda.

Sir Harold Himsworth presided over the Symposium. In his closing remarks Sir Harold Himsworth observed that when, with the introduction of the experimental method into medicine by William Harvey, it became possible for the basic medical sciences to advance rapidly while the clinical branches lagged behind at the observational level. In recent years however it has been possible to apply experimental techniques to the living patient and clinical medicine is rapidly catching up. We are now entering the stage "where it is possible to consider the whole of medical knowledge again as one intellectual continuum." This present symposium is evidence of that fact.³

C.B.F.

ESSAYS IN INDIVIDUAL PSYCHOLOGY. Edited by Kurt Adler and Danica Deutsch. (New York: Grove Press, Inc., 480 pp., 1959. \$2.95.)

In this book Kurt Adler, the son of Alfred Adler, and Danica Deutsch have gathered more than 50 articles written over the years by psychiatrists and psychologists who use predominantly Adlerian concepts and methodologies in handling their psychotherapeutic problems.

The topics discussed in the treatises range over a wide field and are grouped into 4 main sections: philosophical concepts, theoretical principles, therapeutic procedures and case

presentations. One is at once struck by the freshness, directness and clarity of expression as well as the lack of devious thinking, attributes that were so characteristic of Alfred Adler and which apparently have filtered through to his followers. This is indeed admirable when it does not lead to over-simplification or superficiality, pitfalls that have been successfully avoided by all contributors. As a result the overall style makes for lively, "interesting and stimulating reading."

It is very important that a book such as this should have appeared at this time for, as Joseph Wilder states in his introductory remarks—"most observations and ideas of Alfred Adler have subtly and quietly permeated modern psychological thinking to such a degree that—the question is not whether but rather how much of an Adlerian one is." If this is so, and the evidence seems to support this assertion, a presentation such as the one before us is most timely.

In a short review it is impossible to do justice to the efforts that have gone into the work of writing the articles and editing this volume. Suffice it to say that we are presented here not with a text book on Adlerian psychology but rather with a bird's eye view and a description of many of his concepts together with their practical employment.

Most interesting, too, are the articles which link Adlerian Individual Psychology with other orientations, such as those of Freud, Jung, Existentialism, various group methodologies, psychodrama, Meier's intermediary distasteful therapy, Genderson's graphic play therapy and others. This very enumeration shows once again how widely Adlerian thinking has penetrated into virtually all of psychotherapy.

Thus I think that we owe Alfred Adler most humbly a vote of profound thanks. Moreover, it is heartening to know that his daughter Alexandra and his son Kurt, in collaboration with Danica Deutsch and many other psychotherapists are keeping his thinking and methodologies alive and growing by having formed and by directing the Alfred Adler Consultation Center and Mental Health Clinic in New York which perform the double function of therapy and research.

To this reviewer it seems that *Essays in Individual Psychology* should be on the desk (not merely on the shelf) of every psychotherapist, irrespective of his or her specific persuasion or emphasis of orientation.

WILLIAM WOLF, M.D.,
New York, N. Y.

THE ACADEMIC LECTURE

A SOCIOLOGIST'S VIEWS ON PATIENT CARE¹LEO W. SIMMONS²

For twenty-odd years I have owed a debt to American psychiatrists. This invitation to address you gives me the opportunity to acknowledge the debt, and to attempt a small token payment. In the mid-thirties I was fully engaged and quite content in the joint disciplines of anthropology and sociology as they then existed at Yale University. I was at that time invited by the School of Medicine and the Graduate School to fill a joint appointment as "consultant to psychiatry" from the field of the social sciences. For twelve years thereafter I was constantly at the elbow of a psychiatrist or sitting with his patients, reading their records, visiting their relatives, or participating in conferences concerned with their problems. As a consequence, my life interests and my professional career changed substantially. I found myself more and more involved in a discipline that has come to be labeled "medical sociology." And I have moved further and further into the health field until it has become a full-time vocation.

My major debt to psychiatrists, who have treated me so much as a colleague, is for building up within me a deep and abiding interest in the concepts and processes involved in what may be suitably called personalized patient care. They have taught me in an informal, but indelible way, at least 5 cardinal principles: 1. The uncanny uniqueness of every individual; 2. The concept of wholeness of the person with his illness; 3. A profound respect for subjective experiences as they relate to physical and personal welfare; 4. The underlying continuities in life experience, indeed the stronger continu-

ities in the abnormal or atypical experiences; and 5. The scientific expediency of exercising restraints on personal blame in order better to understand individual behavior.

In more recent years I have gone on from psychiatry to follow patients into the general hospitals, taking with me the viewpoints and general principles learned from them. There I have identified myself more closely with the general medical practitioners, with nursing personnel, and, last but not least, with hospital administrators. But always, it has been easiest and most natural for me to identify with the patient and to think as a layman and as a potential patient. It has been most natural for me to "feel like a patient" as I sat and waited with him on the "admission benches"; followed him to the ward and to his bed; waited outside an operating room; sat with the nurse in the recovery room; heard about a favorable or unfavorable prognosis; and sometimes followed the patient to the morgue, heard about his autopsy, and attended his funeral. Frequently it has seemed not too difficult, figuratively, to "crawl into the skin of the patient and to see his experience through his eyes." Whatever I can say is in substance, therefore, little more than the distilled echoes of what has been heard by me in conference with medical personnel about patients or from the lips of patients themselves or their relatives. So please try to think of me for the next few minutes as the voice of patients or their representatives—plain, simple, and to the point, as patients and their relatives are expected to speak in hospital settings.

LAY ASSUMPTIONS CONCERNING MEDICAL CARE

It may be useful at this point to call to your attention a few assumptions presently held more-or-less by the lay public and by potential patients, about medical and hospi-

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Professor of Education (Medical Sociology), Teachers College, Columbia University, New York, N. Y.

tal practice. The assumptions we share as patients, however valid, influence of course our expectations of hospital staffs when we surrender unto them our ailing and handicapped bodies, our street clothes and accoutrements, our stubborn wills, and our bank accounts. These assumptions may serve as a kind of platform for your consideration of the rest of the paper. It must be left with you to decide whether these assumptions on our part square with reality or not in the present state of medical practice. But whether they do or do not, they color our thinking and affect our reactions.

The first assumption, widely shared, is that modern medicine is now able to make new and almost unbelievable contributions to our health. Amazing therapeutic and rehabilitative potentialities appear to be available or in the offing.

At the turn of the century, a high authority on medical care made the statement that, at that time, if a person became ill and sought the services of a medical-hospital team, his chances were slightly better than 50-50 that he would be helped beyond the measure of family and folk remedies.

I remember as a boy, around 1907, passing the local hospital with my father who pointed out that we should go by quietly, as the sign said. He explained that it was the place where "people are taken when they are very sick." He warned me that "many go in and few get out alive." Then he called off names of neighbors who were taken in sick and "carried out in coffins." I was quiet, *very quiet*. I can almost hear him say now, "Son, Stay Out!" He managed to stay out until 82. I stayed out until nearly 40—probably to my disadvantage because of the progress that has been made in medicine. I now say to my offspring, "that's where you were born and it's where you may be kept alive."

Now the odds of having our lives prolonged by putting ourselves into the hands of medical science are very great—so great that for some of us oldsters it may even become too difficult to die in a hospital.

It is reported of a famous American surgeon, that when he became terminally ill and knew it, he persuaded a colleague to promise to take him home to die. When asked why, the surgeon said, in effect,

"When I am nearing the end, I don't want to be stuck full of needles in order to have life drawn out just a little longer."

However that may be, we expect something close to miracles when we enter hospitals today.

A second assumption, shared apparently by many potential patients, is that modern medical personnel, and other health professionals, are not nearly using their full capabilities for maximal health and patient care. We strongly suspect that our professionals are not doing for us what they could do under the proper conditions of organization, environmental control, public support, and interpersonal relations. Sometimes when we potential patients fantasy on what we understand modern medicine can do, and what it often does do, we feel a considerable let-down. We wonder wherein lies the chief flaw between what we could get in health care and what we actually get. We as patients tend to believe that the answer lies more in faulty application than in lack of the basic knowledge and skills. We suspect that defaults lie more in the interprofessional and interpersonal relationships than in poor physical techniques. Simply to illustrate the point, I recently sat beside two doctors at a restaurant counter. The first was commenting on the death of his own father. He said, "Father's physician practiced almost perfect physical techniques," and added, "but his human relations were rotten."

A third assumption follows out of the former two. Potential patients are becoming less and less satisfied with what they get in medical care. They may profess, when interviewed, that their doctor is "all right," but about physicians and hospitals in general, the answer is frequently different.

It is a fact that many patients take with several "grains of salt" the medical public relations' pronouncements that the primary purpose of the hospital is the welfare of the patient. Some of us really suspect that in order better to understand what goes on in the hospital, it is necessary to consider seriously some of the secondary and tertiary interests or forces that "turn the wheels" of the system. In fact, we potential patients might better understand, and be better satisfied with, the hospital service if we

viewed it like any other human institution or organized enterprise, such as a bank, a hotel, a school, or perhaps a good auto service station.

Our fourth assumption is more like a forecast. What the future of medical care in America will be is hard to predict. But as far back as 1926, changes of great import appeared clear to some in positions of medical leadership. The vision reflected in the remarks of George E. Vincent, then president of the Rockefeller Foundation, is not difficult even for laymen to comprehend today. I quote :

It looks as if society means to insist upon a more effective organization of medical service for all groups of people, upon distribution of costs of services over large numbers of families and individuals, and upon making prevention of disease a controlling purpose. Just how these ends will be gained only a very wise or a very foolish man would venture to predict. One thing seems fairly certain : in the end society will have its way.

Our fifth and last assumption is not very complimentary to us potential patients. It is that modern scientific medicine faces substantial resistance, and some subterfuge, on our part in the full and forthright practice of its therapeutic potentials. Resistance ranges from apathy to hidden and unconscious stallings by us patients and our relatives. We also play sometimes for the secondary gains in being ill. Someone has said, perhaps correctly, that in general we patients part into two categories of the "sheep" and the "goats," or the "cooperatives" and the "crocks," at the great divide between a basic desire on our part for cure or for care. It is the care-motivated group among us that constitutes the great challenge in medical application. Hospital staffs are going to have many of us with them for a long time. Should the difficult patients continue to wear the title of "crocks," then there will be a great and growing need for development of the art and science of crockmanship in hospital practice in order to help us cope more successfully with our handicaps.

The fact seems clear that the obstacles to the application of medical and nursing care can be almost as formidable as are those to the discovery of the effective ther-

apies. Let us face it, we are not all willing and cooperative patients, and we often fail to cooperate when it would be far easier for us, were our health problems handled in their early and preventive or corrective stages. In short, the business of patient care is only half accomplished by the discovery of new therapeutic skills. The health professional can still encounter sick and dying people around him, know what to do, and be helpless to do it. He can be held captive and relatively immobile by a complex of lay forces and resistances that are beyond his control.

Do such assumptions as these have a firm basis in fact ? If so, what is the background of the facts ?

THE IMPACT OF CHANGE

The facts are these, in part. Changes are under way in the health field and newer concepts of patient welfare are holding sway. It may sound trite, but it's true and significant, that medicine will move with the times or it will fall behind. In the present pace of change, our professions must all but "run" in order to keep "standing" in their rightful places. The health professions are no exception, for there is no good opportunity to "stand-pat" on patient care. According to Ibsen, "That man is right who is most closely in league with the future."

Change is on the march, with certain broad, "outside" changes that are shaking the foundations of traditional hospital practice. There are other changes within the hospital system that are upsetting the old order of staff-patient relations.

CHANGES OUTSIDE THE HEALTH FIELD

Of the broad, outside changes, first, there is the increased mobility of the population : horizontal mobility in that we shift our homesites repeatedly in the course of a lifetime and a fifth of us change our addresses annually ; vertical mobility in that we strive to move up in the social ladder hopefully at least one rung per generation and correspondingly improve our standards of consumption. We Americans have become, thus, to a high degree doubly nomadic. It is not easy to maintain stability and continuity of patient care in the midst of such accelerated "nomadicism." Such mobility is

bound to upset established norms and expectations in medical practice.

A second broad change is a steady increase in the sophistication of the lay public, associated in part with the higher standards of living and communications, including education. There was a time when the gap between what the physician knew and the general knowledge of the average person was wide indeed and constituted a sort of intellectual aristocracy for the profession. This gap can be illustrated somewhat by the preliterate patient who approached his doctor, gave him his hand, and waited in silence. Holding the hand, the physician asked, "Now what is your trouble?" The patient is said to have replied, "I am just a plain, ignorant man. You know everything. Tell me."

Today almost every physician, even one who practices in a semi-civilized spot in America, faces patients who know, or think they know, more about many matters than their physician can possibly know. One doctor, a general practitioner, recently was heard to comment on how disturbing it could be to observe how learned his patients could appear to be, even about medical matters. He explained that some of them attempted to by-pass his knowledge and skills, diagnosing their ailment, going directly to a designated specialist, and paying only the one bill! Later in the discussion a specialist remarked how some of his patients, in their pseudo-sophistication, prescribe their own treatment—"A little penicillin, please, Doctor." Such instances are extreme, to be sure, but the fact is clear that contemporary Americans, when compared with their grandparents, are increasingly sophisticated and critical about the medical services they receive.

A third broad change affecting the health field is what has been called the commercialization of the professions. At a former time the services of persons in the professions seemed, in a sense, "beyond price." Now the public is coming to see in the professionals, and they appear to perceive in themselves, less of the image of a dedicated servant of the people and more of the air of an astute business man. This is true of professors as of other professionals. Noteworthy instances once were cited of

consecrated men standing for and standing by ideas and ideals of service to humanity, and abhorring the market-place. Many educational institutions gloried in campus characters, firm, professionalized and dedicated, who could not be "moved" by financial offers doubling or tripling their incomes. Such professionals acquired halos and especially in the field of medicine. With the spread of commercialism, these halos are fading for all professionals. Three recent books serve as eye-openers on this subject: *The Academic Market-place* which describes how young professors get their positions and promotions; *The Doctor's Business* which portrays the same market-place approach; and *The Image Merchants* which reflects the superficial, cash-and-carry tactics and philosophy of modern public relations agencies. Under the rising tide of commercialism in America, one may wonder how long even the closely-knit religious orders will be able to preserve much of the image of the dedicated professional that is the heritage of our past. Most professionals, including physicians who are now sometimes labeled "merchants of medicine," are viewed more and more as human beings with typical frailties, but trained and practiced in some marketable skill. This new attitude certainly affects the relationship of the physician to his patient, the nurse to the physician and the patient, and each one of them to the other professionals. The patient or his responsible relative is perhaps made to feel most aware of this commercialized impact upon his welfare. Recently I received a letter from an old acquaintance that read, "We took father to the hospital for ten days. He came out with a small patch on his hip and a \$1000 hole in his pocket."

A fourth change of great significance is the shift in age composition and prevalence of disease in the American population, with communicable diseases declining and long-term illnesses gaining. In coping with communicable diseases health professionals did things mostly *to* or *for* patients; with long-term illness they have to rely more on the continuous cooperation from the patient or his relatives and often beyond the reach of effective supervision. Such a situation calls for new forms of staff-patient relations.

In the fifth place, there is a transition in American thought from a religious-philosophical orientation toward a materialistic and scientific attitude to life and its problems. We are oversold on the idea that science can do almost anything for us—and then find ourselves distraught by the fact of its limitations. Outside its legitimate bounds, the scientific approach alone provides little help and cold comfort: and its limits are always reached in matters of health.

To me it has appeared many times in hospital relations that a major gap occurs between the confidence, attention, support, and even availability of staff services to the patient's body and to the person himself, and this contrast in relationship is especially pronounced when further hope does not exist for survival of the body. The way the average staff copes with the necessity of dying and the problems of bereavement leaves much to be desired and often appears no less than dismal. Indeed, there are grounds for wondering whether most hospitals are suitable places in which to die with any assurance of personal composure and dignity. A sensitive-minded and high medical authority writes:

Most hospital deaths are anything but dignified and the family cannot even get into the room for the oxygen tent, intravenous stands, suction machines, and the sundry rubber tubes protruding from all bodily orifices. Recently a former surgical patient came to the hospital with what bade fair to be his final coronary occlusion. At the time of his death, the wife was across the hall in another room where she had been sent against her wishes to make room for the oxygen tent and technician regulating it; the laboratory technician drawing blood for various chemical tests; the cardiologist, his resident and intern all feeling the pulse or trying to listen to the heart; a nurse giving morphine by hypodermic needle; and a doctor injecting adrenalin into the heart. The scene of confusion was terminated only by the patient's demise . . . The wife was well within her rights to feel cheated out of her last goodbye and to feel hurt at the lack of dignity, propriety, and awareness shown by the medical team. (Bowers, *Interpersonal Relations in the Hospital*, 1960, p. 40.)

Finally, a sixth broad outside change that I wish to call to your attention, is the

growth and spread of organized interest groups. Americans have become a highly organized people, with such groups as organized labor, organized producers and consumers, organized salesmen of goods, and organized professionals. It looks as though it is becoming for us, organize or perish. The union card of a close-knit organization with its pressure apparatus and bargaining techniques and powers seems all but a necessity now for getting our needs, our rights or our dues recognized, at least as we see them. Witness, for example, governments, unions, and other organized interests that are engaged in bargaining for medical personnel, and trying out their own systems of medical care. Must patients, too, organize in order to cope with organizations? I once observed the formation of a union of patients on a ward service. It had its president and vice-president, its secretary, and its grievance committee.

CHANGES INSIDE THE HOSPITAL

But change occurs within as well as outside the hospital system. Permit the cataloging of a few of these.

First to consider is the vast expansion of medical equipment or armamentarium as it is sometimes called. Hospital service has become a giant enterprise, especially when compared to the horse-and-buggy and the little-black-bag that were the stocks-in-trade for the yesteryears. In capital outlay for plant and equipment alone, it has come to rate high up in the order (sixth or seventh) of the country's business investments. Needless to say, the skills, functions, and relationships of professional workers in the field of health have had to keep pace with the expansion in equipment and techniques. Under such conditions medical personnel have tended to become attendants to gadgets and documents as much as or more than to patients directly, and, in the eyes of the patient, doctors and nurses resort more and more to forms of remote control in their ministrations.

In the second place, there is considerable elaboration in the institutionalized routines of hospital services that resemble production-line developments in industry. To a significant degree doctors, nurses, and other personnel have become as cog units in an

evermore tightly structured system. Personnel "run mazes" that pattern their behavior, and perhaps their ways of thinking and feeling about each other and their patients. The freedom of the physician is thereby restricted, the ingenuity of the nurse is limited, and the patient feels that his personal characteristics and interests are stereotyped, slurred over, neglected or squelched. It is now common to speak of the "structure and culture" of a hospital as a phenomenon which, in important respects, is distinct and different from the social structure and culture of the community that surrounds it. It has become part of the task of social scientists to study the institutionalized medical system as such to discover when and where interpersonal conflicts and stresses between medical personnel and patients are primarily the consequence of the system rather than of individual idiosyncracies.

A third change within the hospital has been the rapid increase in the use of professional and para-professional specialties in varied types of patient services. As many as 38 different personnel have been counted as busy about something in a patient's room in a single day. Incidentally a colleague of mine left with one patient a recording machine with instructions for the patient to turn it on and record all that was said to him. An analysis of the record showed that no words at all were passed between the patient and some "attendants" and that most time spent in communication had been with the cleaning woman.

The hospital remains much in the throes of readapting patient care in terms of an increasing host of "specialists" coming and going around the bedside. To these the patient is expected to adapt, chameleon-like, to each in turn. If the patient sustains sufficient composure to observe carefully what goes on around him, he may recognize two types of specialists. There are the professional specialists who have learned more and more about less and less in ailing bodies. They are the experts, and are indispensable and expensive. Then there are the factory-type "specialists" that have been quickly trained with just enough practice to do simplified tasks passably well and under the authority of others. These

"trained ancillaries" have invaded many ranks of hospital personnel and are pressing for prerogatives—and it turns out that they are not inexpensive, especially as they organize union-wise. Such a spawning of professional and para-professional specialism around the patient is a product of our times and constitutes, as yet, unresolved problems in the application of good patient care.

Specialization of both types, with the splitting up of responsibility, leads to a fourth significant factor in the modern hospital. A natural component of specialization is the fragmentation of personal service and with a corresponding pin-pointing of blame within the linked segments of responsibility. It has long been puzzling to me how quickly and precisely the finger of blame is pointed in the hospital. One might wonder if evil motives are attributed more readily in hospitals than elsewhere or if the personnel mistrust each other more than is usual in other environments. Then it might dawn upon one that the practice of blaming personnel is a built-in and cultivated part of the system. It may help to insure discipline but it aids little in the understanding of individual behavior and its effects upon the welfare of the patient.

The phenomenon of blame, and its corresponding guilt complexes and precautionary measures deserves considerable systematic study.

A fifth change to note here is the rapid growth of prepayment plans, group medical practice, and greater involvement of governments in the safeguarding of our health. These three developments carry potentials for profound modifications in staff-patient relations. Refusal to accept patients, threats of discharge, or a label of "discharged against advice," may be "in order" if the patient is a "charity case" or if he is a private patient paying his way on the spot; but these practices carry sour, unfair, and intolerable connotations when the patient has been paying for his hospital care over a period of 10, 15, or 20 years. Moreover, prepayment would seem to call for more attention to personalized patient care.

Consider also the spread of group practice across the country—developments that are tending to combine "packaged bargains"

in patient care through extensions of health services by cooperating specialists. This movement is bound to affect the old hospital-patient relations.

Likewise, the commitments of the federal government to increasing amounts of the health services for expanding segments of the population creates new sets of conditions—and something like a third-party relationship within the old associations—and with both assets and liabilities. Some estimates are that government-sponsored health services in America now cover in some form as much as half or more of the total population.

A sixth and final important change occurring within the hospital and health field is the expanding perspectives on medical care or what constitutes good patient care. The older perspectives focussed on the treatment of acute illnesses; and the hospital first flourished in the care of the emergency ailments, for the mentally ill, and for indigent persons.

Our new medical horizon has vastly enlarged. What has happened is that the concept of patient care has been expanded greatly: to preventive measures on the one hand and rehabilitation on the other. Moreover the views on good patient care throughout the spectrum have been deepened to include whatever the varied specialists can contribute to the welfare of the patient, and this calls for a new kind of team work. To try to fit such contemporary concepts into the traditional pattern of patient care resembles, figuratively, attempting to fill weak, old wineskins with the new, strong wines.

In searching for clarity on the new goals of patient care that the health professionals of tomorrow may be committed to, I came across a useful recent book, *Readings in Medical Care*, edited by a Committee on Medical Care Teachings of the Association of Teachers of Preventive Medicine (1959). Dr. Roger Lee, and Mrs. Lotus Jones in one chapter make the emerging goals of patient care both positive and specific. They are to the effect that good medical care will:

limit itself to the practice of rational medicine based on the medical sciences;
emphasize prevention;

require intelligent cooperation between the lay public and the practitioners;
treat the individual as a whole;
maintain a close and continuing personal relation between physician and patient;
utilize and collaborate with social welfare work;
coordinate all types of medical service; and
make application of all the necessary services of modern scientific medicine to the needs of all the people.

If such is truly in the offing for us, then we laymen have good reason to lift up our heads with hope.

SUMMARY

In summary of the impact of contemporary changes on medical personnel and patient care:

We have saluted medical-hospital staffs for what they now offer for the health and welfare of potential patients.

We faced frankly the great lag between what actually is done and what could be done by a full use of available knowledge and skills.

We called attention to the fact that lay dissatisfaction increases and presses for improvements—and may press harder on the health professionals in the future.

We anticipated that many improvements in patient care can come by means of better application of the existing knowledge and skills.

We expected, also, that improvements in hospital practice are bound to come in one way or another—that in the end society will probably have its way. So we are not pessimists.

We anticipated, on the other hand, that such progress in patient care will occur in the face of some opposition on the part of many potential patients and we hoped, by implication, that systematic study of the social factors involved may speed the orderly progress of hospital-patient relationships.

We have called attention to six broad changes in the social order that have some bearing on medical trends and staff-patient relationships: population mobility—horizontal and vertical; general lay sophistication; commercialization of the professions; shifts in age composition and disease preva-

lence in the population; changes from a religious-philosophical toward a scientific orientation; and the growth and spread of organized pressure groups.

We have also identified specific changes within medical-hospital practice: vast expansion of equipment and capital investment; growth of institutionalization; increase of specialization (professional and para-professional); the fragmentation of responsibility and sharpening of blame potentials; the rapid growth of prepayment plans, group medical practice, and participation of the government in provisions of medical care.

Attention was called also to the fact that new and more challenging concepts of patient care have arisen, expanding the old ideas in comprehensive terms: adding preventive and rehabilitative care to care in the acute stages of illness; calling for team relationships in decision-making and practice; and moving towards group responsi-

bility for the well-being of potential patients.

The impact of such trends and developments on the new physician, the hospital of tomorrow, and patient care of the future will probably be great, however difficult to foresee or to measure now. In a sense we find in the present hospital a "house divided in itself." We hold little hope that smoother "public relations" goes down deep enough to resolve many of these change-determined cleavages. They call for statesmanship in hospital practice more than for salesmanship in hospital service. Your psychiatric skills are much needed in the general hospitals. Not your profundities, mind you, but your simple, tried, and tested principles.

Finally, how interesting it would be to return to this place and to review again these matters twenty or thirty years hence when today's students in the health professions have come to occupy your present important places—and our children are their patients.

STUDIES OF BEHAVIOR AND THE METABOLISM OF INDOLE DERIVATIVES IN SCHIZOPHRENIA^{1, 2}

NYLA J. COLE, M.D., ROGER B. ALLISON, JR., Ph.D.,
MELVIN J. GORTATOWSKI, Ph.D., AND C. H. HARDIN BRANCH, M.D.³

Historically, psychiatric interest in the indole nucleus probably dates back to the original demonstration of the role that nicotinamide and its precursor tryptophane play in producing the pellagrous syndrome of dermatitis, diarrhoea, and dementia. This interest was revived in 1953 when quantities of serotonin (5-hydroxytryptamine), an indole structure, were found in normal brain substance(21). Since then, studies which have outlined the distribution of serotonin in grey matter(3, 4), especially its relationship to such neurohormonal substances as noradrenalin(2, 5), and its high metabolic turnover rate(6), have combined to provoke further interest in indoles. In addition, the recent finding that serotonin, along with noradrenalin and adrenalin, is a strong synaptic inhibitor lends further credence to the possible importance of indole derivatives in mental functioning(7).

The observation(8) that structural analogues to serotonin have a "schizophrenogenic" effect on mental functioning has led to the proposition that some of the hallucinogenic drugs owe their effect to interference with the function of serotonin(9); this proposition is consistent with an anti-metabolite theory of action. Of course, from this observation, speculation has extended to the idea that there may be psychiatric entities whose pathology is based upon some metabolic dysfunction of indole com-

pounds. The demonstration by Gaddum (10) that d-lysergic acid was a serotonin antagonist in vitro did much to further this interest. At the present time, there is a sizable list of chemical materials that are suspected to be either antimetabolites of serotonin in vitro, or psychotogenic, or both(11-22). These are presented in Figures 1 and 2. Note that many of these compounds contain the indole nucleus.

As will be also noted in Figure 2, some of the tranquilizing drugs are implicated in the activity of serotonin. In animal studies, the Rauwolfia derivatives have been demonstrated to cause depletion of brain serotonin(23-25). The phenothiazine derivatives have been shown to block serotonin in vitro, with this blocking ability seeming to parallel their psycho-sedative potency in vivo(14, 15). Iproniazid(26, 27) also plays a role in serotonin metabolism by blocking its degradation; and the administration of iproniazid leads to increased levels of both serotonin and norepinephrine in brain tissue. Lastly, many of the effective antiepileptic drugs(25, 28), e.g., dilantin, mesantoin, etc., are now implicated in raising brain content of serotonin.

These findings have provoked a number of clinical investigations(29-36), which have largely centered around a search for metabolic differences in tryptophane metabolism between psychiatric patients and normal subjects. Some researches affirm differences in indole excretion, others negate it. Our interest in these derivatives began in 1954, when Dr. Marvin Armstrong, biochemist, at the University of Utah College of Medicine observed that mentally defective patients were excreting two unidentified indole acids which were not present in the urine of normal subjects. He later observed the presence of these compounds in the urine of schizophrenic patients. These observations were augmented by studies which showed that one of these indole derivatives, "spot 14," was present more often in schizophrenic and other psychiatric patients than

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² The first report of these studies was presented at the Western Regional Psychiatric Meetings, American Psychiatric Association, September, 1959. These studies were supported by U.S.P.H.S. Grant #M-1165 and by Scottish Rite Foundation Funds. The authors wish to express their indebtedness for the invaluable aid given this project by John D. Benjamin, M.D., Dept. of Psychiatry, University of Colorado School of Medicine, who kindly acted as consultant.

³ Department of Psychiatry, College of Medicine, Department of Biological Chemistry, University of Utah, and Veterans Administration Hospital, Salt Lake City, Utah.

in normal control subjects. These findings suggested a possible relationship between indole excretion and mental disorders and prompted the present investigation. The ultimate goals of our project were : (a) to examine the nature of the above findings, (b) to explore the psychiatric and psychological correlates of the compound, and (c) to identify the chemical nature of the compound.

PROCEDURES AND RESULTS

It is obvious that several variables could be hypothesized to account for the differential presence of the indole derivatives and to serve as possible explanation of the source of variance. These variables include diet, medical and other treatment, length of illness, length of hospitalization, physical activity, bowel activity, *etc.* However, pre-

liminary screening of the effect of EST and other drug therapies, and the effect of institutionalization *per se* in chronic medical patients, did not appear to have a bearing on the observed indole differences.

The next step was to determine whether or not the original findings of the indole-schizophrenia relationship would be sustained with a better controlled sample. Using a "blind" procedure, psychiatric patients and controls were evaluated independently by the biochemist and the psychiatric team. The general procedure was to collect an early morning urine specimen which was coded and turned over to the biochemist. Each subject then received a psychiatric evaluation, followed by psychological testing.

The chemical technique was a modification of the procedure outlined by Arm-

strong(37). Using morning samples, urine was acidified and extracted with organic solvents, and the extracts were subjected to two-dimensional paper chromatography. On spraying the chromatogram with Ehrlich's reagent (p-dimethyl aminobenzaldehyde), the indoles produced color compounds as discrete spots, varying from pink to purple and blue. The two indole spots in question in this investigation were numbered 14 and 15 and are blue and light purple, respectively.

Figure 3 depicts the approximate location of these spots on a chromatogram. Our main attention was turned to spot 14, since

it is the one that appears most discretely and is usually not obscured by drugs ingested by the patient. Rating of indole level was done by visual inspection; scale values ranged from negative to plus 4, depending on color intensity and size of spot.

The psychiatric evaluation consisted of a joint clinical interview conducted by two psychiatrists, with each psychiatrist independently completing a 46-item rating form and arriving consensually at a diagnosis.

The psychological testing consisted of a battery of standard and experimental tests measuring various aspects of cognitive

HALLUCINOGENIC (PSYCHOTOGENIC) DRUGS

FIGURE 2

functioning, such as verbal intelligence, perception, and thought organization. The tests were all administered individually.

One hundred and thirty-five subjects were evaluated independently by the biochemist, psychiatrists, and psychologists. When the blind procedure was broken, analysis still indicated a significant relationship between indole excretion and schizophrenia, thus supporting the original findings. These findings are presented in Table 1.

TABLE 1
INCIDENCE RATES OF POSITIVE INDOLES

	(Original Data) Preliminary Data	(Replicated Data) Project Data
Control Subjects	12% (95)	31% (86)
Non-schizophrenic Psychiatric Patients	55% (31)	26% (19)
Schizophrenic Patients	67% (59)	63% (30)

Table 1 compares the original findings with the replication data. It is to be noted that roughly 2 out of 3 of the schizophrenic patients were indole positive, as compared to 1 out of 3 of other non-schizophrenic psychiatric patients and control subjects. Such factors as length of hospitalization, duration of illness, medications or physical activity did not appear to be significantly related to the indole status.

The relationships between indole status and various psychiatric and psychological variables were determined after about 90 subjects had been processed. The blind procedure was removed at this time in order that the direction of future plans could be assessed. Although 90 subjects had been seen, complete data were available for only 72 subjects. These data were obtained from 30 negative control subjects, 17 positive control subjects, 15 positive psychiatric patients, and 10 negative psychiatric patients.

Fifteen variables were selected and a

FIGURE 3

matrix of intercorrelations was computed. The 15 selected variables included indole status, age, scores on the verbal subtests of the Wechsler Adult Intelligence Scale, a pathology score from the Two-dimensional Semantic Differential (which we have developed and believe measures disturbances in thinking), global clinical ratings of thought disorders based upon Benjamin's Proverbs and the Rorschach, scores on two perceptual closure tests (Gestalt Completion and Mutilated Words), and psychiatric ratings of the mode of problem solving and schizophrenic status. The correlations between indole status and each of the remaining variables are presented in Table 2.

TABLE 2
CORRELATIONS BETWEEN INDOLE STATUS
AND SELECTED VARIABLES

Variable	Correlation
Age	.08
WAIS verbal subtests :	
Information	-.21
Comprehension	-.25
Arithmetic	-.23
Similarities	-.30
Digit Span	-.15
Vocabulary	-.08
Semantic Differential	.32
Proverbs (rated for thought disorder)	.31
Rorschach (rated for thought disorder)	.15
Gestalt Completion	-.11
Mutilated Words	-.16
Solves problems via fantasy	.22
Schizophrenic diagnosis	.42

The signs of the correlation coefficients presented in Table 2 would suggest that psychiatric and control subjects who were negative with respect to indole excretion performed intellectual tasks better and had less pathology in other areas than patients or control subjects who were indole positive. However, only 4 of the variables had correlations which approached adequate confidence levels. These variables included Similarities, Semantic Differential, and the Proverbs and were so related to indole status that a tentative interpretation was made that the excretion of indoles was perhaps associated with a disturbance in thinking. The highest correlation with indole status was obtained from the diagnosis, which expressed once again the relationship

between indole excretion and schizophrenia.

The chemical procedure, upon which the foregoing findings depend, was originally based upon acidification of urine prior to extraction for indole compounds. Studies on the variation of indole level, for a given sample of urine, with careful adjustment of pH, have shown that optimal extraction occurs at a pH of 2.5; at a pH above or below this point, the amount of indoles removed by the solvent decreases. These results are presented in Figure 4.

This demonstration led to a refinement in the biochemical techniques which followed specifically an extraction pH of 2.5, and also led to an alteration in the interpretation of differences in indole excretion between schizophrenics and normal subjects.

FIGURE 4

In view of the apparent dependence of indole level upon the pH adjustment of the urine, the same control group of subjects, which had previously shown the 31% indole positive incidence, was reexamined, using new collections of urine. Most of the controls who were initially positive remained positive, but two out of three of the formerly negative controls became positive. Thus, the normal controls now showed a 75% indole positive incidence with the pH adjustment of the urine to 2.5 prior to

extraction. Using the same technique, it was found that a new group of schizophrenic patients maintained a 67% indole positive status. In other words, the apparent difference between schizophrenics and control subjects no longer existed.

Before the pH modification of the extraction procedure, the most obvious factors that might have explained the above apparent relationship were dietary differences and/or bowel motility, with the possibility that spot 14 represented a product of the activity of intestinal flora. To assess these factors, a group of 19 schizophrenic patients and 8 normal controls were maintained on the same hospital diet for a continuous period of 26 days. Patients and controls ate all meals together. A detailed record of individual dietary differences was kept. On the second day, a 24-hour urine specimen was collected. Beginning on the third day, two grams of achromycin per day, for a total of 5 days, were administered orally to sterilize the gastrointestinal tract. After withdrawal of the antibiotic, a 24-hour urine specimen was collected on the 1st, 5th, 8th, 12th, 15th, and 19th days.

The first column of figures in Table 3 shows the distribution of positive and nega-

tive indole 14 status before achromycin administration. It should be noted that a level of plus 1 or more was regarded as positive and less than plus 1 as negative. On the first day of achromycin withdrawal, the number of subjects excreting indole 14 decreased. This was the case for both normal controls and schizophrenic patients. Gradually, however, the indole 14 status returned to nearly the pre-achromycin level. About 70% of the entire group of 27 subjects, however, showed a change from positive to negative indole 14 excretion with achromycin administration and back to positive within two weeks after discontinuing the drug.

The failure of complete abolishment of indole 14 excretion on treatment with achromycin could possibly be explained on the basis that (a) a previous history of antibiotic treatment of the subject could lead to the presence of resistant strains of the indole 14-producing bacteria; (b) lowered bowel motility results in more bacterial putrefaction, and (c) general physical health and appetite would alter dietary intake.

The data are examined in more detail as shown in Table 4.

TABLE 3
NUMBER EXCRETING INDOLE 14 BEFORE AND AFTER ACHROMYCIN

Subject	Indole 14 Status	Pre-achromycin 2nd Day on Diet	Post-achromycin (Days)					
			1	5	8	12	15	19
Controls (8)	Positive	5	2	3	2	5	7	6
	Negative	3	6	5	6	3	1	2
Patients (19)	Positive	14	7	8	10	15	16	13
	Negative	5	13	11	9	4	3	5

TABLE 4
PERCENT EXCRETING INDOLE 14 BEFORE AND AFTER ACHROMYCIN

Subject	Indole 14 Level	Pre-achromycin 2nd Day on Diet	Post-achromycin (Days)					
			1	5	8	12	15	19
Controls (8)	Negative	37	75	63	75	38	13	25
	+1	25	25	38	25	25	25	38
	+2	13	0	0	0	38	50	38
	+3	25	0	0	0	0	13	0
	+4	0	0	0	0	0	0	0
Patients (19)	Negative	26	69	58	47	21	16	28
	+1	21	26	37	37	37	32	11
	+2	32	5	5	16	21	21	22
	+3	16	0	0	0	16	16	28
	+4	5	0	0	0	5	16	11

It can be observed that in general the schizophrenic patients achieved higher levels of indole 14 excretion than the normal controls within the same length of time (a little over two weeks). Also the patients showed generally higher levels of indole 14 than the normal controls both before and after achromycin. Similarly, in the recheck data where the apparent relationship of the indole-schizophrenia relationship disappeared, it was still found that schizophrenic patients tended to excrete greater quantities of spot 14 than the controls.

If plotted on a graph, the difference might be portrayed as illustrated in Figure 5.

FIGURE 5

Actually two types of differences are present between schizophrenics and controls. In the first place, higher excretion levels are generally observed in schizophrenics. Also, schizophrenics show greater variability in excretion levels as compared to controls.

The most probable explanation for these differences in excretion of spot 14 is one of bowel stasis. Constipated individuals regularly throughout the study showed higher excretion rates of this indole compound. If one adds to this fact the probable change in autonomic nervous system activity with psychic disturbance and/or changes in habits of exercise, decreased bowel motility might account for the variable excretion rates found in schizophrenic patients.

Biochemical efforts throughout this

study⁴ have been directed toward eventual identification of spot 14. Armstrong⁵ has identified spot 14 as indoxyl glucuronide and found it to be a normal metabolic product resulting from bacterial putrefaction in the gastro-intestinal tract.

SUMMARY

1. Urinary indole excretion of spot 14 appears to depend upon the presence of certain bacterial flora in the gut.

2. When extraction of urine for chromatographic examination is carried out at pH 2.5, there appears to be no direct relationship between the appearance of indole 14 in the urine and the mental status classified as schizophrenia.

3. From the dietary drug studies reported, we would conclude that the probable source of this indole derivative that was examined (spot 14) is from bacterial flora acting upon certain dietary substances in the gut.

As Benjamin, Kety (38, 9), and others have pointed out, the area of psychiatric research to date which has a rather fruitless history is the search for definite and discrete biological abnormalities as presumed etiological factors in the development of the schizophrenias. In the main, when rigid controls have been maintained and research design has allowed for examination of all possibilities, an expected primary causal relationship generally fades into being a secondary manifestation of factors intrinsic to the diagnosis of schizophrenia, such as dietary differences, institutionalization, behavioral differences, and so forth. This has been well illustrated recently by the fate, for example, of interest in ceruloplasmin (28, 39) and in phenolic acid excretion (40). In the author's opinion, the particular indole compound we have studied, i.e., "spot 14," can be included in the above category.

STEPS TOWARD THE ISOLATION OF A SERUM FACTOR IN SCHIZOPHRENIA^{1, 2}

CHARLES FROHMAN, Ph.D., ELLIOT D. LUBY, M.D.,
GARFIELD TOURNEY, M.D., PETER G. S. BECKETT, M.D.,
AND JACQUES S. GOTTLIEB, M.D.³

The presumption that some types of schizophrenia may be related to inborn or acquired metabolic errors has been cyclically popular since the time of Kraepelin. As a result of this presumption, many investigations searching for a toxic metabolic factor have been made. Early studies led to no definite delineation of any such defect. A resurgence of metabolic research has occurred during the past decade due to improved methodology and instrumentation in both biochemistry and neurophysiology. The psychotomimetic drugs have also contributed to enthusiasm for biochemical research prompted by their ability to produce symptoms approximating those occurring in schizophrenia. Their chemical structure and action have led investigators to establish models suggesting that a central disturbance in synaptic transmitter substances such as the catechol amines may be present in schizophrenia(1). The Tulane group has reported the extraction of a substance, presumably protein, from the serum of schizophrenic patients which they called "taraxein"(2, 3). When injected into volunteer controls, a psychotic response ensued, characterized by difficulty in thinking and depersonalization. When given to monkeys with electrodes implanted in the septal area of the brain, they showed behavior resembling catatonia and developed slow waves in their EEG's. It should be mentioned that other centers in this country have not been able to duplicate this work(4, 5), although a Swedish(6) group has reported experimental verification with taraxein. Rather than being a simple protein, it would seem

that taraxein is a mixture of as yet unrefined globulin components(7). Freedman and Ginsberg(8) did exchange transfusions between 4 schizophrenic patients and 3 normal adults and produced no significant clinical changes in either group. Winters and Flataker(9) found that rope climbing rats lost their agility when injected intraperitoneally with whole serum from schizophrenic patients. Plants and tissue cultures have been incubated with schizophrenic serum in an attempt to assay growth inhibition or acceleration. The results again have been controversial(10). Luby *et al.*(11) have been unable to demonstrate differences between blood from schizophrenic patients and control subjects using several standard plants bioassay tests exceedingly sensitive to the presence of indolic compounds. Federoff(12), using cultures from strain L mouse cells, reported toxicity highest with the serum of schizophrenic patients as opposed to the serum of normal subjects and surgical patients. Similarly, Martin and Kost(13) demonstrated marked effects of schizophrenic serum on tissue cultures of HeLa cells, even suggesting that their technique might be used as a diagnostic test. Unusual indolic compounds have been discovered in the urine of schizophrenic patients with paper chromatography; McGeer *et al.*(14, 15) reported a number of unusual amines not found in normal urine. To the contrary Cafruny and Domino(16) showed a decreased incidence of a hydroxyindole-like material in the urine of schizophrenic patients. Bercel(17) studied the influence of schizophrenic serum on the behavior of the spider and found that serum from two-thirds of the catatonic cases produced a rudimentary type of web. Serum from other schizophrenic groups and normal subjects had little influence in changing the web patterns. The importance of diet in such studies cannot be overestimated, as evidenced by Kety's(18) obser-

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

vation that these so-called abnormal indoles are related to coffee ingestion.

Studies at the Lafayette Clinic have concentrated on intermediary carbohydrate metabolism(19, 20, 21). A defect in the mechanisms associated with energy regulation was found in the chronic schizophrenic population manifested by an inability to mobilize adenosine triphosphate as an adaptive response to a stressor. Further work revealed that patients stressed with insulin could not shift their utilization of glucose to a portion of the carbohydrate metabolic scheme yielding greater energy production. It became important to know whether this was an enzymatic defect within the cell, or the result of an extracellular inhibitor substance. Crossover experiments incubating the plasma from patients with the erythrocytes of control subjects and vice versa clearly demonstrated that the substance was extracellular and in the plasma of the patients(22). The effects of plasma from patients on oxidative metabolism of chicken erythrocytes was also investigated(23). Plasma from patients produced a more anaerobic form of metabolism than plasma from control subjects.

These experimental results might be interpreted in a number of ways. They suggest that a compound in the plasma acts to prevent more effective utilization of glucose for energy under conditions of stress. Such a factor might be a normal metabolite found in excess in the patient's plasma or else an abnormal metabolite present only in the patient.

This paper is a report of the initial attempts to isolate and determine the chemical structure and mechanism of action of this plasma factor which produces these disturbances in carbohydrate and energy metabolism.

METHODS OF INVESTIGATION AND RESULTS

The three investigatory steps and the procedures for partial identification that have been used so far in order to isolate the factor accounting for the described metabolic defect in schizophrenia are :

1. Separation of serum into protein and non-protein fractions by ultrafiltration.

2. Electrophoretic separation of the serum proteins.

3. Further separation of the active protein fraction by column chromatography using DEAE cellulose.

In order to determine the activity of each fraction following separation, the chicken cell method(23) was used. The chicken cells are a homogeneous medium and are particularly valuable in studying glucose metabolism in that they are nucleated, and therefore catabolize glucose both anaerobically and aerobically. The non-nucleated human erythrocytes catabolize glucose without the use of the most important aerobic pathway, the tricarboxylic acid cycle. The degree of oxidation within the cell (*i.e.*, the rate of function of hydrogen transport) may be determined by measuring lactate/pyruvate ratios. Serum from schizophrenic patients produced lower pyruvate production and higher lactate/pyruvate ratios when incubated with chicken erythrocytes than did serum from control subjects. The measurement of lactate/pyruvate ratios can be used to determine the presence or absence of the "active" substance in each fraction separated. By dividing the lactate/pyruvate ratio of the fraction from the patients by that of the control subjects, one gains an index of the "activity" of the fraction of the patients. When the ratio is higher than one, it indicates an abnormal amount of activity in the schizophrenic sample. Pooled serum from chronic schizophrenic patients and control subjects was utilized for the analyses.

The methods and results for each individual step will now be described.

1. *Separation of serum into protein and non-protein fractions by ultrafiltration.*—The sera from control and schizophrenic subjects were separated into protein and non-protein portions by ultrafiltration using zinc chloride treated cellophane as the filtration membrane. The results of the lactate/pyruvate ratios for the schizophrenic and control sera are reported in Table 1. Since the abnormal activity was found in the protein portion of the serum from the schizophrenic patients, one can conclude that the active principle is of protein structure or is conjugated with a protein.

2. *Electrophoretic separation of the serum proteins.*—(a) Early protein separation pro-

cedures. A Karler Misco Curtain Electrophoresis apparatus was used in the first protein separation procedures. The buffer was 0.01 M barbiturate at pH 8.6. The serum proteins were separated into 17 fractions using 750 volts and 7 amperes. Figure 1 demonstrates the lactate/pyruvate ratios from each schizophrenic fraction divided by the lactate/pyru-

TYPICAL PROTEIN SEPARATION

vate ratios from the corresponding fraction of the control subjects. A value greater than 1 indicates an abnormally active fraction. In this figure it can be clearly seen that this fraction occurred near fraction 6. This fraction contains primarily beta-globulins.

(b) Later protein separation procedures. In order to fractionate larger quantities of serum a Beckman Spinco C. P. electrophoretic cell with a barbital buffer of 0.02 M. at a pH of 8.6 was used. This separation was accom-

plished with 900 volts and 70 amperes. A typical separation is shown in Figure 2. These protein levels were determined by the biuret method(24). With better separation of larger amounts of serum, it was then evident that "activity" was most probably coming out in the alpha globulin fraction (Figure 3). It can be seen that the most abnormal activity is around fraction 9 of the schizophrenic sample, although there is some abnormal activity in the slow gamma globulin (fractions 2 and 3).

3. *Further separation of the active protein fraction by column chromatography using DEAE cellulose.*—The method used was developed by Heath and co-workers(25). The cellulose was suspended in a large quantity of 2N.NAOH for 24 hours and separated by centrifugation. It was then washed with distilled water until the washing returned to pH7. It was then washed 5 times with 0.005M phosphate buffer at pH7, suspended in 0.005M phosphate buffer, and a column 2 inches in diameter and 20 cm. high was poured.

The sample was washed onto the column with two 50 cc portions of 0.005M phosphate buffer. It was then eluted by a gradient elution system containing 2 liters of 0.005M phosphate buffer in flask A into which is siphoned a solution containing 0.04M NaH_2PO_4 and 0.14 M NaCl. Fifty cc fractions of eluate were collected. Protein content of the fractions was determined using absorption at 280 mu. The protein concentrations of the various fractions are shown in Figure 4. Lactate/pyruvate ratios of the schizophrenic fractions divided by lac-

tate/pyruvate ratios of the corresponding fractions from the control serum are presented in Table 2. "Activity" was demonstrated in fraction 3 which as yet has not been identified.

Studies of the physical and chemical properties of the "active" substance.—The "active" fraction was added to chicken erythrocytes and then incubated with 1 label glucose and 6 labeled glucose and the CO₂ measured in the manner described previously. With this method, one can determine the relative amount of glucose metabolized by the Emden-Meyerhof scheme and the hexosemonophosphate

TABLE 3

CO₂ PRODUCED FROM THE 1 AND 6 CARBONS OF GLUCOSE BY CHICKEN ERYTHROCYTES INCUBATED WITH FRACTIONS FROM SCHIZOPHRENIC PLASMA

	Fraction 9	Ratio 1/6
Schizophrenic	1-6870	68.7
	6- 100	
	1-9180	
Normal	6- 70	131.0
Schizophrenic	Fraction 4 1-4035	63.0
	6- 64	
	1-4622	
Normal	6- 100	46.2

Incubation mixture consisted of 4 ml. of chicken erythrocytes suspended in equal volume of 0.9% NaCl, 5 ml. of plasma, 0.05 mc. 1-6 labeled glucose, 1.0 cc. of the appropriate fraction and 0.5 cc. of 1% glucose. Fraction 9 was already proven active by use of lactate/pyruvate ratios from chicken cells. Fraction 4 was an inactive fraction used for comparison.

shunt. Table 3 gives the results of this study, showing that the factor increased the percentage of glucose metabolized by the Emden-Meyerhof scheme, thereby decreasing the amount converted to ribose. This was the same type of reaction noted previously in plasma from control subjects when subjected to insulin stress and which occurred in the plasma of the schizophrenic patients both before and after stress.

Since the factor from the serum of the schizophrenic patient appeared to be either an alpha or beta globulin and because many of these are glycoproteins, tests for N acetyl mannose amine (sialic acid, neuraminic acid) were performed on all the separated fractions from both patients and control subjects. Sialic acid levels were determined by two independent methods, because of the lack of specificity of each method. One method employed modified Ehrlich's reagent(26) and the other method used diphenylamine(27).⁴ The levels of sialic acid per gram of protein for the various fractions from both patients and control subjects are shown in Figure 5. There is approximately 2½ times as much sialic acid in the active fraction from the patients as in the corresponding control fraction. In the other fractions there were no significant differences.

Studies of the physical properties of the active fraction reveal that it is unstable above pH 9 and below pH 6. It is most stable at 4° C. and within a few hours is destroyed at room temperature or by freezing. It can be dialyzed at pH 7.5 for 3 days at 4° C. without destruction. If a prosthetic group is involved it must be tightly bound. As was noted above, the active compound appears to be an alpha globulin or is some substance attached to an alpha globulin.

The concentration of this fraction by the methods described above was one thousand fold (7 gm. of protein gave approximately 7 mg. of the active factor). However further purifications must occur before any statement can be made regarding blood level concentration.

⁴ The sialic acid standards were supplied by Gregory Duboff, Ph.D.

FIGURE 5
MGS. SIALIC ACID PER GRAMS PROTEIN IN VARIOUS FRACTIONS

DISCUSSION

The separation procedures have led to the isolation of a factor in the serum of schizophrenic patients which has a significant effect on metabolism as measured by lactate/pyruvate ratios in the chicken erythrocyte. The procedures employed have revealed that this substance is most probably an alpha globulin or a prosthetic group attached to an alpha globulin. It remains stable at 4° C. at a pH between 6 and 9, but is readily destroyed at room temperature and with freezing. The alpha globulin may have a prosthetic group which resembles sialic acid. The factor also stimulates energy production by forcing glucose through the Emden-Meyerhof scheme, rather than the hexosemonophosphate shunt. This is also characteristic of the plasma from schizophrenic patients. This metabolic effect is characteristically seen in control subjects under stress. This suggests that the active principle in patients with schizophrenia may reflect a disturbed

mechanism for adapting to stress. Further investigation is necessary to clarify this possibility.

What is this factor and its significance for the understanding of the schizophrenic illness? It must be emphasized that, as yet, the factor has not been identified, although several of its characteristics have been defined and its activity greatly concentrated by the separation procedures. Also, although it appears to be definitely related to the previously described metabolic defects in schizophrenia, its meaning for the production of schizophrenic symptomatology in its many diverse aspects is not known. It may be that this is a substance normally present in the serum of all individuals, but quantitatively elevated in the schizophrenic. This elevation could be due to excessive production of the substance or the inability of the schizophrenic to metabolize or detoxify it. It is possible that this factor appears in normal persons after severe stress, as suggested by the metabolic

shift from the hexosemonophosphate shunt to the Emden-Meyerhof scheme that appeared under stress in the control subjects. This, however, remains to be proved since serum of stressed control subjects has not yet been separated in the manner described for the serum of patients. Studies of this type are now in progress.

On the other hand, this factor may be an abnormal substance, never found characteristically in normal persons, which produces a significant and diverse effect on metabolic processes in the schizophrenic patient. This could be an abnormal protein, or an abnormal prosthetic group attached to a protein. It is possible that such a prosthetic group is related to sialic acid. The actions of sialic acid are unknown, but it is found in connective tissue, and more importantly as a normal constituent of the macromolecular brain gangliosides.

What is the relationship of this factor to other toxic factors reported as occurring in schizophrenia? This is in no way clear, although this factor could account for some of the results reported in other bioassay techniques, such as the rat climbing test and disturbed web patterns of spiders, that have suggested an abnormal effect of schizophrenic plasma. Taraxein may also contain this active principle. Inconsistencies in reports regarding toxicity of serum may be related to the lability of the compound in that it is so easily altered by changes in pH and temperature. Transfusion replacement studies in which the blood of a normal subject is given to replace the blood of the schizophrenic patient produces no consistent improvement. This abnormal substance most likely continues to be produced by the person with the schizophrenia and would therefore quickly prevent any replacement effects.

Much investigation remains to be done before one can understand the nature of the active factor and its significance in the pathophysiology of schizophrenia. With further isolation and definition of its characteristics, behavioral assays will assume crucial importance in determining its precise role, whether primary or secondary, in this disorder. Further research on the factor's behavioral effects and the mechanism of its action is presently underway.

SUMMARY

1. The steps in the separation of a factor in the serum of schizophrenic patients have been described.

2. This factor has a significant effect on metabolism as measured by lactate/pyruvate ratios in the chicken erythrocyte and the stimulation of energy production by forcing glucose through the Emden-Meyerhof scheme, rather than the hexosemonophosphate shunt.

3. This factor is readily affected by pH and temperature, remaining relatively stable between pH 6 and 9 at 4° C. It is probable that this is an alpha globulin or a prosthetic group attached to an alpha globulin.

4. The significance of this factor for the schizophrenic illness has not yet been clarified. This may be a substance normally present in the serum of all individuals, but quantitatively elevated in the schizophrenic because of excessive production or its failure to be metabolized or detoxified. On the other hand, this may be a qualitatively abnormal substance characteristic of schizophrenia.

5. The possible relationship of this factor to other reported toxic factors in schizophrenia has been discussed.

6. Further biochemical studies are in progress to identify the subject, as well as behavioral studies to ascertain its relationship to the production of disturbances in overt behavior.

LONGITUDINAL CLINICAL AND NEUROCHEMICAL STUDIES ON SCHIZOPHRENIC AND MANIC-DEPRESSIVE PSYCHOSES¹

SAMUEL BOGOCH, M.D., Ph.D., KARL T. DUSSIK, M.D.,
CHRISTA FENDER, M.D., AND PETER CONRAN, M.D.²

This laboratory is studying structure-function relationships in psychiatric patients with reference to the nervous system itself. Despite the inherent difficulty in doing structural studies on the nervous system *in vivo*, such studies are necessary if primary structure-function relationships in the nervous system in terms of behavior are to be approached. Evidence in recent years has emphasized the relative autonomy of the nervous system with reference to peripheral organs and fluids. This physiological autonomy, frequently referred to in terms of the Blood-Brain Barrier concept, has its basis in the fact that most substances pass in and out of the nervous system relative to the blood with difficulty. There is less likelihood therefore that biochemical correlates of either normal mental function or a disturbance thereof, central nervous system in nature, will be detected as readily in its primary form by studies on peripheral organs and fluids. With this in mind, we have been investigating the structure and function of some little-studied substances, native to the nervous system itself and relating these chemical studies to detailed longitudinal clinical investigations on the same individual psychiatric patients. This report will give only a brief outline and a few examples of the combined clinical and neurochemical approach which is being followed.

STUDIES ON BRAIN GANGLIOSIDE

The carbohydrate-containing macromolecules of the nervous system, both glycolipid and glycoprotein in nature, are being investigated. One of these substances, occurring in high concentration in grey matter of brain, called brain ganglioside, has been

studied in terms of its structure, histological localization, and physiological function. By the isolation of a previously unrecognized constituent of brain ganglioside, gangliocerebroside, the formulation was made of the repeating unit of this substance(1). The chemical structure of brain ganglioside showed it to contain water-soluble constituents (neuraminic acid, hexosamine, and hexoses) on one surface of the molecule, and lipid-soluble constituents (sphingosine, stearic acid) on the other surface of the molecule, suggesting to us that brain ganglioside might be a membrane substance involved in receptor and transport functions in nerve cells(1, 2). By virus studies we have shown that brain ganglioside is indeed a receptor for certain neurotoxic viruses(3, 4). By pharmacological studies with smooth muscle preparations(5) it was possible to show that brain ganglioside has marked stimulatory function in a membrane-active system, the clam heart, suggesting that brain ganglioside may be involved in transmission phenomena in the nervous system. In immunological studies, specific antibodies to brain ganglioside were prepared by us and these were used with fluorescent antibody techniques to demonstrate the nerve cell body localization of brain ganglioside(6). Thus, it has been possible, by utilizing several methodologies, to go from the determination of molecular structure, to physiological function, and then back to the histological localization for a substance native to brain. These studies provide evidence that brain ganglioside and substances chemically akin to it may be involved in important regulatory functions in terms of controlling the entry and egress of a number of important constituents in the nervous system. These functions are referred to collectively as the Barrier-Antibody System(7, 8). If such is indeed the case, the relevance of these functions to mental health and mental disorder requires careful exploration.

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

EARLIER STUDIES ON NEURAMINIC ACID IN CEREBROSPINAL FLUID

There is one compartment in the nervous system which is readily accessible to repeated sampling in both man and animals without untoward physiological effects. This compartment is the cerebrospinal fluid (CSF). Our initial studies on "total neuraminic acid" in CSF in 1957, demonstrated an accumulation of this substance in CSF with age, with the maturation being apparent by 7 or 8 years of age(7, 8). Schizophrenic adults showed lower values for this substance relative to controls and comparable only to the values found in some children under 7 years of age. One group(9) working without double-blind controls, did not observe low values as consistently in a small group of schizophrenic patients. A second study(10) was unable to observe differences but used a correction factor for glucose which we have shown to be inadequate(14). On the other hand, our finding of low values for neuraminic acid in CSF in schizophrenic patients has been independently confirmed by two other laboratories(11, 12),³ although one of these confirmatory studies(11) also employed correction factors for glucose which we have shown to be unsatisfactory. The initial findings have also been confined in our extended series of cases now numbering 1,024.

Longitudinal studies(13) on schizophrenic and other psychiatric patients over weeks and months demonstrated that these low values were "group consistent" for all but 8% of untreated individual schizophrenic patients, and that with treatment only some 7% more demonstrated increased concentration of "total neuraminic acid" bringing the values into the normal range. By "double-blind" careful clinical evaluation it was observed that clinical change was frequently temporally coincident with and qualitatively (and occasionally quantitatively) related to the change in the concentration of "total neuraminic acid."

All the above early studies used methods which determined both bound and free neuraminic acid, together with some other substances chemically related to neuraminic

acid(13, 14). By the careful quantitative fractionation procedure subsequently developed in this laboratory(14, 15, 16), it has been possible to define the relative contributions of each of these fractions. In addition, it has been possible to obtain quantitative measures of the amounts of two other substances, the hexosamines and hexoses which are bound in combination with neuraminic acid in the macromolecular glycoproteins of CSF. These new quantitative studies have, in addition to supporting the earlier findings on neuraminic acid in schizophrenics, provided data on the altered neurochemistry in other psychiatric diagnostic groups: in chronic brain syndromes, manic and depressive psychoses, as seen in the concentrations of protein-bound hexosamine and hexose. Furthermore, maturation phenomena have been shown for protein-bound neuraminic acid, hexosamine, and hexose, which are of interest in relation to the possible relevance to psychological maturation(8).

THE GLYCOPROTEINS OF CEREBROSPINAL FLUID

The quantitative fractionation procedure which has been developed for CSF(14) is briefly shown in Figure 1. Whole CSF is lyophilized and dialyzed quantitatively, the whole non-dialyzable fraction (Fraction I) is then partitioned into a water-soluble fraction (Fraction G) and a very small insoluble fraction (Fraction P). Fraction G is further partitioned by column chromatography into 6 glycoprotein fractions. Fraction II, the whole dialyzable material, is then treated on column chromatography with the resultant separation of cations, anions and neutral sugars. Free neuraminic acid from 0 to 12 μ g. per cc. of CSF can be demonstrated in this way. Table 1 illustrates the large amount of quantitative data in terms of total solids, nitrogen, phosphorus, hexose, reducing sugars, hexosamine, and neuraminic acid, previously unavailable, and now available on each of these sub-fractions of CSF. It may be noted that the analyses indicate that Fraction G is a glycoprotein fraction particularly rich in carbohydrate components when compared with comparable glycoproteins of blood. Table 2 shows the electrophoresis and quantitative elution of hexose and neuraminic

acid of Fraction G. It may be seen that normal specimens show the highest concentration of these carbohydrates bound to protein in the α_2 and α_1 globulin regions, whereas schizophrenic patients and some other mental hospital patients show the highest concentration in the β -globulin zone, rather than in the α_2 and α_1 globulin zone. Table 3 shows the further partition of Fraction G by IRC-50 column chroma-

tography(17) into 6 subfractions differing in mobility and in absolute concentration of protein-bound hexose. Each of these subfractions has been further subdivided by paper electrophoresis. By this combination of ion-exchange chromatography and electrophoresis the presence of at least 20 individual glycoproteins has been demonstrated in CSF(17). Furthermore, these fractions differ between individuals. Table

4 shows the quantitative amount of protein-bound hexose, hexosamine, and neuraminic acid in individual specimens of CSF. The ratios of these substances in terms of molecular amounts of each vary markedly from individual to individual over the range of

hexose: hexosamine concentration of less than 1:1 through almost 10:1. Most people show ratios of 1:1 or 2:1. The high degree of chemical individuation observed is of great interest since these are chemical constituents of the nervous system itself. The

possibility that this potential for chemical individuation is related to chemical bases of individuality must now be considered.

GLYCOPROTEINS IN PSYCHIATRIC DISORDERS

Following the observations of 1958, when the absolute amounts of these substances are compared in groups of psychiatric disorder, certain unique patterns emerge. Table 5 shows the absolute concentrations of protein-bound hexose, hexosamine, and neuraminic acid in individual psychiatric patients and general hospital controls. It may be seen that patients with manic psychoses demonstrate very high values for macromolecular hexose. Macromolecular hexosamine is elevated in both chronic brain syndromes and in manic psychoses, but is significantly lower from the control group in untreated schizophrenic patients. Macromolecular neuraminic acid is also low in untreated schizophrenic patients.

With treatment, schizophrenic patients synthesize (or release) glycoproteins with normal or even greater than normal amounts of hexosamine, but containing still significantly lower levels of neuraminic acid (18).

Longitudinal careful clinical follow-ups in double-blind studies with neurochemical studies have now been in progress for as long as 2½ years on approximately 150 patients. Figure 2 shows an example of the relative constancy of these constituents in a single depressed patient in an 11-month period and the marked change which occurred accompanying gross functional change, in this case the change from marked depression to the normal affective or slightly elated state. This change was accompanied by a 500% increase in the absolute amount of protein-bound hexose despite the fact that there was no change in the total amount of glycoprotein present per cc. of CSF. Thus, it is not that more

glycoprotein is present, but that a very different glycoprotein appears accompanying this functional change. The reverse change is seen also: that is, a drop in hexose accompanying the reverse functional change from a hypomanic to a depressed state in another patient who received no specific therapy. The changes in protein-bound hexose and hexosamine appear to relate to mood and other secondary symptomatology and have occurred with drug therapy as well as with electroshock therapy and spontaneously. On the other hand, levels of protein-bound neuraminic acid do not vary with secondary symptomatology but appear to be related to the level of maturity in terms of classical psychological and psychoanalytic periods of development and other more primary personality characteristics. Figure 3 shows two cases with the diagnosis of paranoid schizophrenia treated with insulin therapy. It may be seen that whereas both began with typically low amounts of protein-bound neuraminic acid and hexosamine, the changes in these glycoprotein patterns with treatment were quite different in the two cases. Thus, the first case, representing 85% (Table 5) of schizophrenic patients thus far studied, showed a 700% increase in the amount of hexosamine synthesized in protein-bound form, but no change in neuraminic acid. This patient did not improve. The second case, representing about 15% (Table 5) only of schizophrenic patients studied, showed a somewhat lesser increase in hexosamine, but there was in addition a marked increase in the neuraminic acid bringing it into the normal range. This patient showed a marked clinical improvement.

WORKING HYPOTHESES

These preliminary studies suggest the working hypothesis that there is a disturbance in the synthesis or maintenance of both macromolecular hexosamine and neuraminic acid in schizophrenia and that the disturbance in hexosamine can be overcome (indeed "overcompensated for") with treatment, but that the disturbance in neuraminic acid is most often refractory to therapies presently available. Since hexosamine is a synthetic precursor of neuraminic acid, this accumulation of a precursor, without

the accumulation of its derivative, suggests the possibility of an enzymatic block.

It must be emphasized that these are neither more nor less than working hypotheses and their theoretical nature must clearly be distinguished from the quantitative nature of the experimental data from which the hypotheses arise. Most important, these examples are given in order to demonstrate that these new methods indicate a highly individual extensive chemical geography of native central nervous system constituents and provide a unique opportunity to study primary correlations between neurochemical and clinical events in individual patients over long periods of time.

SUMMARY

Macromolecular glycolipids and glycoproteins of the nervous system itself are being investigated in terms of their chemical structure, histological localization, and physiological function. Parallel "double-blind" clinical and quantitative neurochemical studies in psychiatric patients and controls have indicated a high degree of chemical individuation of these nervous system constituents, which may have relevance to individuality. In addition, distinctive patterns of these constituents have been observed in chronic brain syndrome, manic, depressive, and schizophrenic patients, and controls. These new quantitative methods provide a unique opportunity to study longitudinally primary correlations between neurochemical and clinical events in individual patients.

ACKNOWLEDGEMENTS

It is a pleasure to acknowledge the chemical technical assistance in these studies of Mr. Peter Belval, Mrs. Claire Grunberg, Miss Dorothy Winer, Mrs. Barbara Schupak, Mrs. Judith Davidson, and Mrs. Annette Klein. CSF samples were also obtained with the assistance of Dr. A. Crocker and Dr. R. C. Payne of the Children's Medical Center, Dr. M. Nicholson, Dr. J. Crehan, and Dr. C. A. Fager of the New England Deaconess Hospital, and the members of the staff of the Massachusetts Mental Health Center. This work was done with the support of United States Public Health Service grants and the National Association for Mental Health through the Scottish Rite Research Committee.

DISCUSSION

R. A. CLEGHORN, M.D. (Montreal, P. Q.).—These three papers demonstrate the critical influence of method on the progress of research. The development of new techniques in biochemistry in the past 15 years permits the measurement of organic substances in minute amounts, which was inconceivable prior to that time. This has led to a variety of renewed attacks on problems of mental illness. Frequently the concept underlying these approaches is not new, as has been pointed out with respect to the possibility of a toxic metabolic factor in schizophrenia.

The utilization of such techniques as have been described in these papers makes certain demands of clinical investigators. It is fair to expect that they will be applied with a rigour no less exacting than that exercised in other biological fields, and presented in as comprehensible a form as possible. An audience composed of psychiatrists cannot be expected to be as familiar as yet with the intricacies of

modern biochemistry as applied to its discipline, or with many of the newer terms in common parlance among biochemists. To be frank, I do not feel that certain of the three papers just read gave sufficient thought to the process of lucid communication of material which might well be expected to be somewhat unfamiliar to a large section of today's audience. Doubtless these are difficult data to present simply, but even in reading the manuscripts I found the going heavy at times. Furthermore, viewers cannot be expected to extract significance from columns of data. If any of the authors be even slightly offended by my somewhat sententious and gloomy preamble, I will not be upset if they put this down to the discussant's halting understanding.

My interpretation of a discussant's duty is that he should provide critical appraisal and, where possible, an assessment of implications of the work under consideration.

Dr. Frohman spoke in his introductory paragraph of the use of psychotomimetic drugs in "physiologic amounts." In order to be precise it is appropriate to point out that no dose of these drugs constitutes a physiologic amount. They produce effects in minimal or greater pharmacologic amounts only. A few lines later, these authors refer to Woolley and Shaw as having established: "models suggesting that a central disturbance in synaptic transmitter substances, such as catecholamines, may be present in schizophrenia." Actually, the Woolley-Shaw reference is to serotonin, an indole ethylamine, which is not a catecholamine. These are perhaps simple errors in exposition, but not happy examples of rigour.

In discussing the putative role of abnormal indole compounds from schizophrenic patients, the authors mention McGeer, *et al.*, who reported unusual amines in the urine. Unhappily, they seem to be unaware that a later paper from McGeer's laboratory back tracks on their previous position. They state in 1959 (*Canad. J. Biochem. Physiol.*, **37**, pg. 1493) that: "The differences found between the schizophrenic and normal extracts have not been stressed. Difficulties in quantitation and the uncertain origin of the spots, coupled with the relatively small number of extracts studied, make us feel that significant conclusions can be drawn only after further work." Acheson, working in the same laboratory, was unable to confirm McGeer's original observations on urine. By dealing in such detail with controversial work the Lafayette group have not obtained support for their own endeavours which should, of course, be judged on its own merits. In previous work along the lines of that reported

today, Dr. Gottlieb and his associates have reported that a chronic schizophrenic population has alterations in certain aspects of carbohydrate metabolism. This seemed to be associated with an unknown component in their plasma.

The present study represents an attempt to isolate this factor, using recognized techniques which they describe. It appears from their investigations that there may be a substance, either an alpha globulin or something associated with this protein, which alters the ratio of lactate to pyruvate produced by the chicken's erythrocyte. They say that it appears to be related to previously described metabolic defects in schizophrenia. Unfortunately, as their own review emphasizes, these "defects" are still highly controversial, with various findings denied by apparently equally reliable workers. I would personally be happier if they had demonstrated that the plasma from patients with a variety of recognized infectious and metabolic diseases had been examined for this abnormal protein. There are also criticisms which might be levelled at their interpretation of the fractionation of proteins, *e.g.*, the graphs submitted do not always bear out the direction the authors are pointing to. The five runs in Fig. 1 are five quite different patterns, and it requires a great deal of intuition to find a common point among them. The situation is somewhat better with the Spinco electrophoretic separation (Fig. 3). One might have been better pleased with a larger number of cases.

One great difficulty in assessing the results is the authors' use of ratios of *numbers*; indeed, also ratios of ratios. It is necessary to have some indication of the absolute figures and the normal variation also.

Finally, the *numbers* are the amounts of lactic and pyruvic acids in chicken erythrocytes under specified conditions. According to the authors, the ratio of these indicates "the degree of oxidation within the cell (*i.e.*, the rate of function of hydrogen transport)." The lactic/pyruvic ratio simply does not measure this, and saying it does not make it so. At best, the lactic and pyruvic acid content of the cells incubated with glucose represents a balance between a great many cell constituents which basic research is constantly exploring further.

Research in psychiatry cannot make advances on the basis of rough-and-ready approximated definitions, so that, suggestive though this work may be, one cannot say that it yet means that there is an established metabolic fault in schizophrenia.

I am most unhappy with the authors' in-

ference that the active principle they find in schizophrenic plasma, "may reflect a disturbed mechanism for adapting to stress." As long as that word "stress" is used indiscriminately, the actual mechanisms may not be examined properly.

The experimental findings of Dr. Frohman and his group are undoubtedly interesting but they have lost emphasis in being too closely associated with speculative explanations.

Controversy is a characteristic of science and one depending on a variety of factors such as subtleties of technique, accuracy of performance, and the intrusion of the investigator's emotional investment, usually in an hypothesis. The paper read by Dr. Cole demonstrates one way of dealing with conflicting reports. The introductory paragraph refers to 37 relevant papers, ignoring detail but highlighting points pertinent to the study to be reported. This is entirely legitimate and leaves the audience free to contemplate the results of the studies presented. The examination of the patients and controls by a "blind" procedure inspires confidence. The replication of the original finding supplied support for the initial data which indicated that one of the indoles in the urine was present more often in patients than in controls. Then the biochemists' regard for exactitude spoiled this promising picture. By extracting the urine at the demonstrated optimum pH, many of the previously indole negative controls became positive. Thus the difference between patients and controls disappeared. It must have been disappointing but it was science. In the exercise of another control measure it was shown that an antibiotic with activity on intestinal flora, where indole producing bacteria flourish, caused a decrease in the incidence of indole positive urines in both patients and normal individuals. The conclusion that the source of the indole studied is from the gut is modest but it puts a nail in the coffin of an elusive red herring. In this presentation of negative results one sees the operation of a highly important facet to progress in research.

Exciting though the third paper is, I confess to some blocking at my blood-brain barrier. The concatenation of unfamiliar and complicated chemical terms makes the ego and the id sound like H_2O . However, we must open our intellectual maws and get on with the job of incorporating this novel biochemical bolus.

The findings reported by Dr. Bogoch are based on studies of well over 1,000 cases. This is a reassuring population sample. To summarize his results briefly we see that :

1. The value for total neuraminic acid in the C.S.F. was low in cases of schizophrenia and chronic brain syndrome. This low value increased with improvement in a few cases.

2. The hexosamine content of C.S.F. was also lower in untreated schizophrenics than in controls. It rose with treatment, both in cases which improved clinically and those which did not. Contrary to the low level found in schizophrenics, hexosamine was elevated in both manic psychoses and chronic brain syndromes.

3. Cases of manic psychoses showed high values for C.S.F. macromolecular hexoses. This value decreased with the alleviation of the hypomanic and the onset of a depressed state.

4. The authors relate the level of protein bound neuraminic acid more closely to the level of "maturity" than to what they call secondary symptomatology and mood. In the cases studied, they point out that of the schizophrenic patients improving there was a marked increase in the neuraminic acid, bringing it within normal range. Contrariwise, the changes in protein bound hexose and hexosamine ap-

peared to relate more closely to mood and other secondary symptoms, and might change with treatment despite the absence of improvement.

Under the label "Working Hypotheses," Dr. Bogoch and his associates suggest that an enzymatic block occurs in schizophrenia, preventing the elaboration of neuraminic acid from its precursor hexosamine in certain cases. Hence, while this constituent may accumulate, it does not necessarily follow that its derivative, neuraminic acid, will increase. They urge a clear distinction be maintained between their quantitative data and their theory. This is wise counsel for all workers and might be summarized as maintaining the distinction between content and concept.

In conclusion, I would like to express the hope that, as these biochemical studies get on to firmer ground, a closer association be made with clinical assessment of mental status. In initial stages, this is understandably subordinated, but ultimately much will be gained by keeping the patient in the picture.

PSYCHOLOGIC FACTORS AND PSYCHIATRIC DISEASE IN HYPEREMESIS GRAVIDARUM: A FOLLOW-UP STUDY OF 69 VOMITERS AND 66 CONTROLS¹

PHILIP W. MAJERUS, SAMUEL B. GUZE, M.D., W. BRADFORD DELONG,
AND ELI ROBINS, M.D.²

Many reports on hyperemesis gravidarum suggest that it is either caused or greatly influenced by psychologic stress and emotional tension (1-9). At the same time, there are other reports that indicate that hyperemesis gravidarum is unrelated to psychologic and emotional factors (10-13).

The evaluation of psychologic factors is difficult, particularly when adequate control groups are not considered at the same time, as has usually been the case. Further, it is desirable to minimize or eliminate the influence of the vomiting and associated discomfort, themselves, upon the patient's emotional state. These considerations, plus the absence of any published psychiatric follow-up studies, suggested that such a follow-up of a consecutive group of women with hyperemesis gravidarum and controls would be of value. It would permit an assessment of the relationship between this disorder and clinically evident psychiatric illness as well as between hyperemesis gravidarum and various psychologic and social factors when the complicating factor of the hyperemesis gravidarum was in the past. Clearly, the results of such a follow-up study could not finally answer the question whether or not acute emotional tension or stress might have initiated the hyperemesis gravidarum. Nevertheless, it could answer the question whether or not there is an association between the excessive vomiting and clinically evident psychiatric disease, on the one hand, and between the hyperemesis and chronic psychologic difficulties, on the other hand.

The present investigation was designed

to follow and study a group of women with hyperemesis gravidarum and compare them with a group of controls for the prevalence of psychiatric illness and for various psychologic, social, marital and medical factors.

In a previous paper (13), we reported on the prevalence of psychiatric illness among the first 48 vomiters and 45 controls. We found no differences between vomiters and controls in the prevalence of any psychiatric disorder except for hysteria which was encountered in 15% of the vomiters and 2% of the controls. Using a one-tailed test of significance, this difference by the Chi square method was significant at the .05 level. It was concluded, therefore, that in the great majority of cases hyperemesis gravidarum is not a manifestation of clinical psychiatric disease and that in the few cases in which it may be a manifestation of psychiatric illness the only illness involved is hysteria.

Another finding presented in our previous paper was the greater prevalence of hyperemesis gravidarum among ward patients compared to private patients.

Since our original sample included only 14 white vomiters and 14 white controls, in the present study we extended our observations to include additional white vomiters and controls. This report then will deal with the psychiatric and psychologic findings of our entire group of vomiters and controls.

METHOD

Selection of Patients and Controls: The sample consisted of all patients admitted to St. Louis Maternity Hospital with hyperemesis gravidarum during 1954-55 reported previously and all white patients with hyperemesis gravidarum admitted during 1956-57. We selected controls by matching each vomiter with the next patient admitted to the hospital with a normal full-term delivery of the corresponding ward or private status.

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² Respectively: Fourth year student; Associate professor of psychiatry; Fourth year student, and Professor of psychiatry, Washington University School of Medicine, St. Louis, Mo.

Part of this work was done during the tenure of a Medical Student Research Fellowship, United States Public Health Service.

There were initially 81 vomiters and 81 controls. After we began the study, we discovered that one control had suffered from pyelonephritis during the index pregnancy and she was therefore excluded from the study leaving 81 vomiters and 80 controls. Of these, 87 were white and 74 were Negro women; 92 were ward patients and 69 were private patients. Interviews were held with 35 or 83% of the white vomiters, 35 or 78% of the white controls, 34 or 87% of the Negro vomiters, and 31 or 89% of the Negro controls. Reasons for not interviewing patients included: patient not located, 3 cases; obstetrician refused permission, 3 cases; patient moved more than 250 miles away, 17 cases; and patient refused interview, 3 cases. Thus 84% of the original sample were interviewed. There were 20 women who had moved more than 250 miles away of whom we interviewed 3. This left 141 women within the St. Louis area of whom we interviewed 132 or 94%. The ages of vomiters and controls were similar.

A further comment is indicated concerning the appropriateness of our control population. The criteria for selecting our controls were presented above. Since many of the mental, social, sexual and familial factors studied may vary with socioeconomic and sociocultural status, it is important to assure similarity of status of vomiters and controls. We compared our vomiters and controls in terms of their educational level, their husbands' educational level, and their husbands' occupational classification without finding significant differences.

Seven percent of the vomiters and 15% of their husbands were college graduates compared to 10% of the controls and 18% of their husbands. The corresponding figures for high school graduates were 38% of the vomiters, 47% of their husbands, 45% of the controls, and 37% of their husbands. Among the vomiters, 48% of the husbands were skilled workers or higher (categories 0-5 of the United States Department of Commerce) (14), while the corresponding figure for controls was 52%. Even when whites and Negroes were considered separately, no significant differences were found.

Criteria of Diagnosing Hyperemesis Gravidarum: The patients were selected on the basis of their having been discharged with a diagnosis of uncomplicated hyperemesis gravidarum. Patients with coexisting illnesses (e.g., pyelitis, pyelonephritis) and patients with toxemia of pregnancy were excluded from the sample. The literature is vague about the diagnostic criteria for hyperemesis gravidarum and since many obstetricians and obstetric residents were involved in the admission of patients, the diagnostic criteria used were varied. Nevertheless, there is no doubt that these women were severe vomiters. Although many of the hospital charts were incomplete in one or more of the significant items that would have permitted evaluation of the severity of vomiting, 58% of the charts presented evidence of acetonuria on admission and 44% of the charts carried notation of significant dehydration. In 38% of the charts there was noted significant weight loss which was over 4.5 Kg. in 2/3 of the cases. These are minimal figures since many of the charts carried none of these notations either positively or negatively, while others carried one or all of the above items.

Further evidence of the severity of symptoms is available from the interview data. When asked why they first consulted an obstetrician at the time of the index pregnancy, 82% of the vomiters reported that they went because of symptoms (nausea and vomiting) in contrast to only 15% of the controls ($P < .01$). The controls most often consulted their obstetricians because they thought it was the thing to do (49%) or because they wanted to find out if they were pregnant (36%). As further evidence of the differences between patients and controls, 64% of the controls reported either no nausea and vomiting during pregnancy (34%) or nausea only (30%). Obviously, there were no such patients among the vomiters ($P < .01$). More than half the vomiters (54%) had nausea and vomiting over half of the pregnancy while only 12% of the controls vomited for this period of time ($P < .01$). The frequency of vomiting was much greater in the vomiters than in the controls with 99% of the former vomiting more than once a day. Only 14% of the controls vomited more than once a day

($P < .01$). Thus it seems safe to conclude that the patients selected by the divergent diagnostic criteria of many obstetricians did have severe vomiting with their pregnancies.

Follow-up Interview: The patients were interviewed from 2 to 4 years after their hospitalization for hyperemesis gravidarum. The interviews were conducted largely in the patients' homes, and occasionally a third person was present. Three patients were interviewed at the hospital either because they were coming to visit their doctor or because they were hospitalized for other reasons. Three interviews were conducted by long distance telephone. We attempted to reach the other patients who lived over 250 miles away by telephone but were unsuccessful because they either had no phone, or were out of the country with their husbands in military service, or could not be personally contacted.

The interviews were primarily clinical in their orientation and were structured so that the same areas were systematically studied in the same order in each woman. Significant positive and negative answers were explored in detail. Questions were asked relating to medical and psychiatric symptoms, past illnesses, operations, hospitalizations, pregnancies, marriages, attitudes toward nursing, relationships with husbands, sexual behavior, and psychologic adjustment. The answers were scored as yes or no after review by each of the authors and the data coded and placed on IBM cards which were sorted and analyzed.

Diagnostic Criteria: The criteria for diagnosing psychiatric illness were those of Wheeler, *et al.* (15) for anxiety neurosis, Purtell, *et al.* (16) for hysteria, Langfeldt (17) for schizophrenia and Cassidy, *et al.* (18) for manic-depressive disease. It should be noted that these criteria relate only to specific medical and psychiatric symptoms, their intensity and attendant disability. Whenever a patient did not meet these criteria, she was placed in one of the following groups: no psychiatric disease, borderline anxiety neurosis, probable hysteria, or undiagnosed. A patient was considered to have borderline anxiety neurosis if she had a few symptoms characteristic of anxiety neurosis but did not have the car-

dinal symptoms or enough of the others to permit a definite diagnosis. We believe that with further study, some of these patients would be regarded as clinically well and some as having mild anxiety neurosis. A patient was considered to have probable hysteria if she was definitely suffering from a chronic psychiatric disorder that had many of the features of hysteria but with some of the typical criteria absent. Unlike the borderline anxiety neurosis group, this group if followed further would almost certainly continue to show significant psychiatric disturbance and would not be considered clinically well even if a definite diagnosis of hysteria could still not be made. A patient was considered to have no psychiatric disease and to be clinically well if she had no psychiatric symptoms or only occasional, mild, inconstant symptoms that did not seem severe enough to suggest borderline anxiety neurosis. Patients who were placed in the undiagnosed group were felt to have a definite psychiatric illness which could not be diagnosed with certainty.

Statistical Methods: Comparisons were made between vomiters and controls by using the Chi square test with Yates correction for continuity. The probability level of $P < .01$ was selected as the level of significance since so many correlations were done. One would expect 1/20 of the correlations to be significant at the $P < .05$ level of significance; we found 4 correlations significant at the .05 level of significance and since over 100 Chi square tests were done, we felt that $P < .01$ would include only significant results. Since there were no significant differences in our results when the two races were analyzed separately, we combined the white and Negro women and are presenting the data in terms of all vomiters compared to all controls.

RESULTS

CLINICAL DISORDERS AND SYMPTOMS

Diagnostic Groups: In the entire group of 135 women interviewed, 69 (50%) had no psychiatric disease and another 13 (10%) had only borderline anxiety neurosis. Of the remaining 40%, 26 patients had anxiety neurosis (20%) and 10 (7%) had hysteria or probable hysteria. The other 18 patients

(13%) were felt to have definite psychiatric illnesses which could not be specifically diagnosed.

There was no significant difference in the overall prevalence of psychiatric disease between the two groups: 55% of the vomiters and 44% of the controls. There was also no significant difference between vomiters and controls so far as the following individual psychiatric diseases are concerned: anxiety neurosis, 23% of the vomiters and 15% of the controls; borderline anxiety neurosis, 7% of the vomiters and 12% of the controls; manic-depressive disease, no vomiters and 1% of controls; undiagnosed psychiatric illness, 13% of the vomiters and 12% of controls. Although there is a suggested difference in the prevalence of hysteria and probable hysteria, 12% of the vomiters and 3% of the controls, this difference is not significant. There were no significant differences between Negro and white women in the overall prevalence of psychiatric illness or in the prevalence of any specific psychiatric illness.⁸

Gastrointestinal Symptoms: The women were questioned about gastrointestinal symptoms which occurred when they were not pregnant. There was no significant difference between vomiters and controls as to food idiosyncrasies, nausea and vomiting, "upset stomach," "indigestion,"

"stomach pain," "stomach trouble," or constipation.

Menstrual Symptoms: A complete menstrual history was taken from all patients. There were no significant differences between vomiters and controls in the frequency of dysmenorrhea (71 vs. 52%), feeling weak and sick with periods (57 vs. 46%), having to lie down for more than half a day with periods (49 vs. 47%), feeling tense and jumpy with periods (54 vs. 55%), menorrhagia (22 vs. 21%), amenorrhea for 3 months or more when not pregnant (7 vs. 8%), and irregular menses (22 vs. 23%).

Psychologic Symptoms: Vomiters did not differ significantly from controls with respect to being nervous (61 vs. 49%), crying easily (71 vs. 62%), being easily depressed (57 vs. 50%), being shy and sensitive (30 vs. 44%), having their feelings easily hurt (60 vs. 38%), and being easily upset or irritated (51 vs. 36%).

SOCIOECONOMIC STATUS OF VOMITERS⁹

In the original sample from 1954-55, there were 58 vomiters, of which we interviewed 48. Of the original 58, however, 40 were ward patients and 18 were private patients. During these two years, 4,660 ward patients and 4,936 private patients were admitted to the Obstetric Service of St. Louis Maternity Hospital. Thus, despite a nearly 1:1 ratio of ward to private admissions in the overall admissions, the ratio among the vomiters was over 2:1. The hospital does not keep overall statistics of racial distribution but the Chief of the Service estimated that about 85% of the ward patients and about 5-10% of the private patients were Negro (19). Of the 40 ward vomiters 35, or 88%, were Negro which is about the estimated percentage of Negro patients in the overall ward admissions. Of the 18 private vomiters 4, or 22%, were Negro, which is higher than the percentage of Negro private patients estimated above. The small number of patients and the absence of accurate data concerning the racial distribution of all obstetric admissions make it difficult to estimate the significance of these figures, but they certainly do not confirm the viewpoint (8) that hyperemesis gravidarum is more prevalent in upper socioeconomic levels.

In the second portion of our sample, from

⁸ In our previous paper, we called attention to the higher prevalence of psychiatric illness among the Negro controls (51%) compared to the white controls (14%). We had no explanation for this apparent difference but since the difference had markedly diminished with the increased size of our white sample (the prevalence among white controls rose to 37%) it was probably only a chance variation resulting from the small size of the sample in the first study. Further, in our previous paper, we noted that when the white vomiters and controls were compared separately, there was an excess of total psychiatric illness in the vomiters, 56% versus 14% ($P < .05$). When the patients with hysteria were eliminated, the significant difference disappeared but there was still an increased occurrence of psychiatric illness in the white vomiters (44%) as compared to the white controls (14%). With the increased size of our white sample we found that 51% of the vomiters and 37% of the controls were psychiatrically ill, a difference that is not significant; and when the white hysterics are removed, the figures are 45% of the vomiters and 35% of the controls, an even smaller difference.

1956-57, there were 23 vomiters, of which we interviewed 21. The total sample of 23 vomiters was divided into 6 ward patients and 17 private patients. All of these patients were white, by our selection criteria. Using the same estimates of racial distribution as above and the figures for all ward and private admissions for the years 1956-57 (3487 ward admissions and 5386 private admissions), we find that the overall ratio of white ward to white private admissions was 1:10, while the ratio of white ward to white private vomiters was 3.5:10. Again these data, while difficult to evaluate because of the uncertainties referred to above, do not support the idea that hyperemesis gravidarum is more prevalent in upper socioeconomic levels.

PREGNANCY, CONTRACEPTION AND NURSING

Primiparity, Abortion and Stillbirths: The vomiters and controls were compared as to the frequency of primiparity and a history of abortion or stillbirth. The proportion of vomiters who were primiparous at the time of the index pregnancy was 31% while the corresponding figure for the controls was 20%. Up to the time of the index pregnancy, 26% of the vomiters and 24% of the controls had had an abortion or stillbirth. These figures were increased to 32% for vomiters and 27% for controls by the time of the follow-up interview. These differences are not significant.

Vomiting with Other Pregnancies: There was one striking difference between the vomiters and controls so far as their pregnancy histories are concerned: while 53% of the controls had never vomited with any other pregnancy, only 13% of the vomiters gave such a history ($P < .01$).

Contraception: Forty-nine per cent of the vomiters and 35% of the controls used contraceptives; while 15% of the vomiters and 18% of the controls practiced coitus interruptus. These differences are not significant.

Planning of Pregnancy: The data indicate that 36% of the vomiters and 38% of the controls wanted and planned the index pregnancy; 38% of the vomiters and 44% of the controls did not plan but wanted the index pregnancy once it was achieved; and 26% of the vomiters and 18% of the controls

did not want and did not plan the index pregnancy. These differences are not significant.

Twenty-nine per cent of the vomiters and 15% of the controls had had at least one pre-nuptial conception. These nearly always preceded marriage to the father. So far as the index pregnancy is concerned, 12% of the vomiters and 3% of the controls conceived prenuptially. Although these differences are suggestive, they are not significant.

Nursing: The results show that there were no significant differences in intention to nurse the index child (vomiters 47% vs. controls 53%), actual nursing of the index child (33 vs. 44%), belief that nursing is better for baby (62 vs. 67%), belief that nursing is a pleasure for mother (48 vs. 64%) and belief that nursing is good for mother (39 vs. 58%).

MARITAL AND SEXUAL ADJUSTMENT

Divorce and Separation: At the time of the index pregnancy, 19% of the vomiters and 14% of the controls had had a divorce or separation due to marital discord. These were scored independently, i.e., when separation preceded divorce, it was not scored. At the time of the interview these figures were 23% for the vomiters and 15% for the controls.

Trouble with Husband: At the time of the interview, 30% of the vomiters and 23% of the controls reported current troubles or difficulty with their husbands—this was the present husband for the women who had been divorced previously.

Sexual Adjustment: This was assessed in terms of the following: desire for less coitus (20% of vomiters vs. 23% of controls), never initiating love-making (33 vs. 32%), enjoyment of coitus less than husband (29 vs. 30%), complete absence of orgasm (6 vs. 8%), achievement of orgasm less than half the time (28 vs. 32%), coitus primarily to please husband over one-quarter of the time (30 vs. 35%), and dyspareunia (23 vs. 30%). None of these differences is significant.

RELATIONS WITH MOTHER AND MOTHER-IN-LAW

The relations with mother and mother-in-law were evaluated by a series of ques-

tions summarized as follows: mothers reported to have had any negative attitude toward index pregnancy (20% of vomiters vs. 16% of controls), mothers-in-law reported to have had any negative attitude toward index pregnancy (23 vs. 20%), mothers reported as being nagging, dominant or offering unsolicited advice (38 vs. 58%), patients indicating a recognition by herself or husband that there was some dependency present in the relationship with mother (49 vs. 54%). There were no significant differences.

DISCUSSION

Clinical Disorders: The fact that 45% of the vomiters were without psychiatric illness at the time of follow-up study indicates that hyperemesis gravidarum is not exclusively related to chronic psychiatric disease. Nor is it related to the following specific disorders: anxiety neurosis, manic-depressive disease and schizophrenia.

The incidence of hysteria and probable hysteria was higher among vomiters (12%) than controls (3%). This difference is not statistically significant although a trend is suggested. In our first paper (13), we reported that 15% of the vomiters and 2% of the controls had a diagnosis of hysteria or probable hysteria. This difference was significant at the .05 level if a one-tailed test of significance was applied. Increasing the size of the sample did not appreciably change these percentages and a two-tailed test still failed to achieve significance.⁴ This suggested correlation between hyperemesis gravidarum and hysteria involves only 10 of the 135 women in the study. It cannot be evoked therefore as a general explanation for hyperemesis gravidarum. Furthermore, as indicated in our previous report, it is possible that our results merely reflect the greater propensity for women with hysteria to be hospitalized for any reason (16). That hyperemesis gravidarum did not

cause the hysteria is evidenced by the fact that hysteria preceded hyperemesis gravidarum in all 7 cases where this information was available.

The only clinical symptomatology that differed in the vomiters and controls was the much greater prevalence of vomiting with other pregnancies in the vomiters (53%) than in the controls (13%). Furthermore, vomiters tended to have more severe and prolonged vomiting than controls in the other pregnancies. These findings are consistent with the reports of others (20). Other gastrointestinal symptoms, history of menstrual disturbances, and occurrence of psychologic symptoms did not show significant differences between the two groups.

Socioeconomic Status: The conclusions of our previous paper on the socioeconomic status of patients with hyperemesis gravidarum are further supported by this extended study. Our data indicate that hyperemesis gravidarum does not occur more frequently in private patients than in ward patients. These results are in contrast to those reported by others (8), but are consistent with the findings of Kassebohm and Schreiber (10) who reported on a series of patients from a New York hospital serving patients of low socioeconomic status only.

Other Findings: We found no significant differences between vomiters and controls when the two groups were compared with respect to primiparity, abortions and stillbirths, contraception, attitudes toward and planning for pregnancy and nursing, separation and divorce, trouble with husband, sexual adjustment, and relations with mothers and mothers-in-law.

The absence of significant differences between vomiters and controls with respect to psychiatric illness, psychologic symptoms, socioeconomic status, and the other factors of personal and social adjustment noted above is in contrast to many of the recent papers on this subject. Our results, however, are based upon the systematic study of a group of *consecutive* vomiters and a group of *consecutive* controls; both groups selected by objective, *non-psychologic* criteria. We have found no other reports of similar series of consecutive vomiters and controls selected and studied in this way. None of the reports suggesting an associa-

⁴One of the two control patients with hysteria in the second half of the study however, was a woman who had had severe hyperemesis gravidarum in the past, vomiting continuously through the day all through pregnancy with each of 7 pregnancies. She had been hospitalized elsewhere on occasion and was bedridden under a doctor's care during the index pregnancy. If this woman is included with the vomiters, the results become 13% vs. 1.5%. (In this case, $P < .05$.)

tion between hyperemesis gravidarum and psychiatric or psychologic difficulties is based upon such criteria of selection and control.

As mentioned earlier, the results of this investigation can only apply to the question of an association between hyperemesis gravidarum and persistent psychiatric illness and chronic psychologic maladjustment. It cannot apply to the possible association between hyperemesis gravidarum and acute psychiatric illness or psychologic difficulty. The next step, therefore, is to apply these same selection criteria to another group of consecutive vomiters and controls and to study these women at the time of the hyperemesis gravidarum. Such a study is planned.

SUMMARY AND CONCLUSIONS

1. This report is based upon a systematic, clinical study of a group of consecutive women discharged from the hospital with the diagnosis of uncomplicated hyperemesis gravidarum compared to a group of consecutive controls selected by taking the next admission to the hospital of a normal, full-term, uncomplicated pregnancy in the same ward or private status.

2. The study involved a personal clinical interview with each woman 2 to 4 years after discharge from the hospital: 84% of the original sample were found and interviewed; 94% of the women who remained within 250 miles of the hospital were found and interviewed. We thus studied 69 vomiters and 66 controls.

3. The interviews were clinical in their orientation and covered the following areas: medical and psychiatric symptoms, past illnesses, operations, hospitalizations, socioeconomic status, pregnancies, nursing, contraception, marital and sexual adjustment, relations with mothers and mothers-in-law, and personal psychologic adjustment. Each area was systematically covered in the same order in each woman.

4. There were no significant differences between vomiters and controls with respect to overall psychiatric illness nor with respect to any individual psychiatric illness.

5. There were no significant differences between vomiters and controls with respect to other gastrointestinal symptoms, men-

strual disorders or psychologic symptoms.

6. There was no evidence that the prevalence of hyperemesis gravidarum was higher in women from upper socioeconomic levels.

7. There were no significant differences between vomiters and controls with respect to primiparity, abortions and still births, contraception, attitudes toward and planning for pregnancy and nursing, separation and divorce, trouble with husband, sexual adjustment and relations with mothers and mothers-in-law.

8. Vomiters were significantly more likely to vomit with other pregnancies than were controls.

9. There were no significant differences between vomiters and controls to suggest that there is any association between hyperemesis gravidarum and chronic psychiatric or psychologic disorders.

THE IMPACT OF RECENT RESEARCH DEVELOPMENTS ON PRIVATE PRACTICE¹

MILTON ROSE, M.D., Ph.D., Dr.P.H.,² AND MARY ANN ESSER, A.B.³

In the last 10 years psychiatry has entered a new phase. The physiological approach to the study and treatment of mind appears to be gaining on the psychological approach in interest and prestige. This impression is gained from contacts with practicing psychiatrists, but until the present study was undertaken,⁴ the extent of the increasing emphasis on physiology in psychiatry was not fully apparent. In our century, psychodynamic psychiatry has spearheaded the expansion of psychiatry as a medical specialty. Indeed, psychiatry has been virtually identified with "dynamic psychiatry" among physicians, behavioral scientists of all kinds and the sophisticated public.

The psychological approach to mental illness has been assumed by other physicians and by the lay public to be based on a theoretical foundation similar to that found in other branches of medicine, and psychiatrists are pictured as doing for mental illness what other physicians do for physical illness. That is, the psychiatrist is thought to apply treatment for the purpose of alleviating symptoms and curing an illness, the cause, symptoms and cure all being of a psychological rather than a physical nature. Thus, a phobic state may be diagnosed from its symptoms, its cause ascertained from the patient's recital of his history, and appropriate treatment instituted. The treatment will be directed toward the development of insight by the patient into the psychological forces producing his symptoms, so that knowledge of specific causes is only obtained over a period of time, and improvement in symp-

toms comes about as this understanding is achieved. More traditional medical measures, such as drugs, may also be used, but these will be purely ancillary or perhaps "shot in the dark" measures when psychotherapeutic measures fail.

Since this is the picture many people, lay and medical, have of the basically psychological nature of theoretical and clinical psychiatry, it appeared to us of great interest to learn just how much effect recent fundamental and widely-publicized developments in the physiological, chemical and pharmacological aspects of psychiatry have had on the thinking and treatment methods of practicing psychiatrists. Recent evidence seems to point to a certain amount of change in practice and in the kind of topics included in the psychiatric literature. A study of the actual therapeutic methods used by psychiatrists in the treatment of various common mental disorders ought to provide information, at least inferentially, about the theoretical convictions of psychiatrists and the way in which these convictions influence actual treatment methods. This paper is the result of such a study, carried out by means of interviews with practicing psychiatrists in the Mid-Peninsula part of the San Francisco Bay Area.

METHODS

Twenty-five psychiatrists, age range from 32 to 55, all practicing in the San Francisco Mid-Peninsula area, were interviewed. These psychiatrists were chosen at random and represent about 50% of the private practicing psychiatrists in the area. The interviews averaged an hour and a half or two hours in length.

The education and professional training of the group are up to the standards of superior American medical schools and psychiatric training programs. All doctors questioned are members of, or are eligible for, membership in the American Board of Psychiatry and Neurology. All except one, who is just beginning private practice, are busy and presumably successful. All but

two of the psychiatrists included have received some type of didactic psychotherapy as part of their preparation for psychiatric practice. Many of them were analyzed by accredited Freudian psychoanalysts. A high proportion of the group, about 85%, had applied to an American psychoanalytic institute for candidacy and nearly all had been rejected. Three had begun as candidates but had discontinued this association. No full-fledged psychoanalyst was a member of this randomly chosen group, although there are such practicing in the area.

All the psychiatrists interviewed were personally known to the interviewer (M.R.), but the professional and personal relationship was in no case closer than that of fellow-practitioners in the same medical specialty in the same part of the Bay Area. Everyone interviewed was thoroughly cooperative and from all appearances answered the questions freely and fully. Most of those interviewed said that no one had ever before asked them how they practiced their specialty, and they were pleased to talk about it.

Four leading and fairly specific questions, most of them having several parts, were asked. Two of the questions were factual and two were specific but were phrased to elicit opinions. No statistical analysis of data was made, even where this could have been done by the application of small sample theory. For example, no quantitative breakdown was made of the number of psychiatrists using specific drugs for specific syndromes, but it was determined that everyone in the group does use drugs in treating patients suffering from the disorders mentioned by name in the questions.

The questions asked were :

1. Do you use drugs in your practice ? Under what circumstances ? How often ? Specifically : sleeping pills ? tranquilizers ? anti-depressant drugs ? other ?

2. What is your treatment approach to : schizophrenia ? depressions ? anxiety states ? Does your approach depend on your decision as to the cause of the disorder ?

3. Should psychiatric residency training include more physiology, biochemistry, etc. ? Is such training now "top-heavy" with psycho-

dynamics, in view of current trends in physiological research in psychiatry ?

4. Along what lines or in relation to what problems would you like to see future developments in the field of psychiatry ?

Questions 1 and 2 are complementary and are designed to give factual information about actual practices. Question 3 asks for an opinion, and question 4 is also aimed at bringing out an opinion and leading to a general discussion of the main issue of this paper : that is, what is the relation of theoretical convictions to actual treatment methods in the private practice of psychiatry ?

RESULTS

The results obtained in the interviews are summarized in the form of 4 statements which give the main points made virtually unanimously by the psychiatrists questioned.

1. These psychiatrists are primarily psychologically oriented, but they deem physical and pharmacological methods useful, and in fact rely quite heavily upon them in daily practice.

2. Both psychotherapy and drugs are used by all of them, in varying proportions depending on individual taste and judgment, and largely symptomatically. The most common indication for the use of drugs is the severity of the symptoms.

3. As a group, these psychiatrists are aware of, and respectful of, recent developments in physiological and pharmacological aspects of psychiatry, but they are not motivated to exert more than casual effort to learn about the basic concepts and hypotheses involved. They admit a greater interest in the subject than before the advent of the tranquilizing drugs.

4. Their first concern is for the development of knowledge in the behavioral sciences as these are related to psychiatry : psychodynamics, sociology, anthropology, and so forth. Of secondary but serious interest is the continuation of research in the physiology of the nervous system and related organs.

The group is primarily psychologically oriented, as would be expected in view of the great stress in nearly all hospital training programs on understanding the pa-

tient and helping him to understand himself. These psychiatrists use the familiar psychodynamic principles and techniques, varying them according to how they "feel" about a patient, a process that is largely intuitive. With many seriously sick people, especially those wracked with anxiety or depression, the psychiatrists tend to be actively encouraging and to offer specific advice as to the conduct of the patient's life. The technique may vary from moment to moment, depending on clinical exigencies.

These psychiatrists are thus essentially empiricists, showing great adaptability and flexibility in the application of those therapeutic means at their disposal. One psychiatrist expressed it this way :

Psychotherapeutically I treat everyone differently and essentially on a symptomatic basis. I am passive and mild when this approach seems called for and very active and bold when the occasion requires this technique.

Drugs are employed either as a last resort, when the patient is found not to be responding to psychotherapy, or as an "opening gambit" early in therapy, sometimes on the first visit and often in response to a request from the patient. If all goes well, however, that is, the patient is satisfied and the course seems favorable, then psychotherapy remains the method of choice. Some of the reasons given for using drugs under certain circumstances were :

"... to alleviate incapacitating symptoms."

"... whenever I want to make the patient feel better, especially if the patient is depressed or anxious."

"I use drugs symptomatically, especially with depressive and anxiety symptoms."

"... to keep the patient functioning."

"... as an adjunct to psychotherapy, as a preparatory thing. For example in excited states, depressions, or in schizophrenia."

Phenothiazines are widely used in schizophrenia, and last year the amine oxidase inhibitors were cautiously used for depressive states. Electric shock treatment is used rather occasionally, mainly for depressions, and is administered in local hospitals by resident staff members. The psychiatrists in our group gave the impression of becoming more physicians, less psycholo-

gists, as their experience increased. They tended to become more active in their dealings with their patients, and to use drugs more often. Only two out of the entire group said that they would never give a physical examination to a psychiatric patient.

It is evident that these psychiatrists regard psychotherapy in its various forms as the hallmark of the psychiatrist, and they consider it his most effective therapeutic tool. They tend to consider psychotherapy as in some way more fundamental, that is, as dealing with causes, while drug therapy is superficial treatment of symptoms. But in most cases, they seemed ambivalent about this point, and their statements were generally guarded. Typical remarks were :

"If causes can be got at at all, they are psychodynamic."

"You can't often determine the cause, but if you do, it will be psychodynamic."

"Drugs and psychotherapy are not mutually exclusive. But psychotherapy is more fundamental. Causes are mostly psychodynamic."

This emphasis on psychotherapy, combined with a considerable appreciation of the usefulness of drugs, is reflected in the answers to the question about psychiatric residency programs. The general feeling was in favor of more emphasis on traditional medical subjects than has been customary in these training programs, but it was not felt that these programs at present actually place too much emphasis on psychodynamics. Most members of the group were familiar with the chemical vocabulary involved in current psychopharmacological research, though the amount of systematic study of the subject appeared to be meager. It was of interest that all felt that a lecture on physiological or pharmacological topics would today draw almost as large an audience as the more traditional lectures on psychodynamic subjects.

Particularly striking were the answers to question 4, on hoped-for developments in psychiatric research. Here, the unanimous first thought and demand was for more research in the psycho-social aspects of psychiatry, rather than on physiological aspects. Most of the suggestions for research subjects brought out strongly the need to

"know what goes on in the patient" engaged in psychotherapy. What accounts for success in some and not in others? Are some psychotherapeutic methods better than others and if so why?

In order to gain further knowledge about the interpersonal process, of which psychotherapy is one aspect, our psychiatrists appear to favor researches where variables are controlled and results quantified, as in clinical psychology and sociology, rather than the traditional introspective psychological studies. The statements were at times contradictory, the humor of the contradiction being recognized almost as soon as the words were uttered. For example:

First, I believe research should go in the direction of the borderline between sociology and psychiatry—but this would not pay off in the intellectual understanding of psychiatry, I am afraid.

About 25% were in favor of research designed to relate psychodynamic phenomena to physiological events, as in so-called psychosomatic syndromes such as hypertension and peptic ulcer. True to their basic training as physicians, all subjects agreed that physiological research is important, even the very few who claimed that they themselves seldom use drugs. There was a strong tendency, however, to assign most physiological research to people in other disciplines. As one of the group put it, "I am not especially concerned about it because it will take care of itself," that is, non-psychiatric scientists of various kinds will surely pursue the relevant problems.

CONCLUSIONS

On the basis of these interviews with a group of psychiatrists which can be considered, we believe, as representative of such specialists in private practice, it appears that the psychotherapeutic side of practice is mainly empirical and consists largely of suggestion and the transmission to the patient of the psychiatrist's wisdom, gained from wide professional experience with many people. While it is difficult to determine the exact content of psychotherapy from interviews such as these, it does appear that psychodynamic theories,

though widely popular, are in practice difficult to apply as specifically as the psychiatrist would like.

There appears to exist a not inconsiderable amount of doubt and confusion among these psychiatrists about the exact nature of the ills they are called upon to treat and about the clinical usefulness of their theoretical formulations and of the various therapeutic measures available to them. This confusion is evident from statements made in the interviews and by some of the practices described. Thus, nearly all these psychiatrists use drugs with definite success in treating mental illness, especially the more severely incapacitating types, yet they say, at the same time, that these illnesses are basically psychological and psychotherapy is the fundamental treatment. They assume that psychotherapy is the treatment of choice, yet they express a wish to know how effective psychotherapy is and how it can be evaluated. They would like to know more about "what goes on in the patient" during psychotherapy, but no one expressed a wish to know how the drugs work which are helpful in relieving many psychiatric symptoms, often dramatically and for long periods of time. There was no feeling that these newer drugs are a mere "flash in the pan," but there was no indication that the efficacy of the drugs suggested to the psychiatrists any implications about the nature of the psychiatric disorders under discussion.

This investigation, then, informal and limited in scope as it was, shows fairly clearly that the relation between a psychiatrist's theory and his actual use of various therapeutic methods is not so simple and scientifically justifiable as one could wish. These psychiatrists find that clinical necessity often leads them to use methods which their theory says should be unnecessary and indeed should not be successful. They find, furthermore, that the therapeutic method their theory says is fundamental and should be most effective cannot usually be applied with any specificity and often may be a failure. They find that they do not for the most part know just how or why they help their patients, and yet help them they do.

It has been said that psychiatry has entered the "take-off" phase of development, during the past 10 years, and we can hope that the extraordinary rate of progress of the "take-off" will continue. It is encouraging to learn that this progress is seen not only in research reports but in the everyday work of the practicing psychiatrist. Whatever the lag between theory and practice, and whatever confusion this lag may engender in the minds of those who must deal with the sick patient, the psychiatrist has shown himself in this study to be in the best tradition of the medical practitioner who, to quote Dr. Alfred Stillé, must never forget that "it is still no small portion of his art to rid his patient's path of thorns if he cannot make it blossom with roses."

DISCUSSION

J. M. COTTON, M.D. (New York, N. Y.).—Speaking directly in terms of the title of Dr. Rose's paper, I think one can summarize this study by saying that the impact of recent developments in neurophysiological research upon private practice has been very small.

In Dr. Rose's sample the standard pattern would appear to be one in which the therapy is primarily psychotherapy of an opportunistic variety styled to fit the individual needs of the patient as intuitively perceived by the therapist. There is no reason to doubt that this is a typical sample.

Dr. Rose notes, with some regrets, the absence of a truly scientific approach in psychiatric practice. I wonder if this concern is justified:—I recall a distinguished and successful physician in a large Southern city who was reputed to have given every patient who came to him the same prescription regardless of the symptoms or findings on examination. This prescription was a combination of a small amount of bichloride of Mercury and sodium iodine and was thought at that time to be useful in tertiary syphilis. Now the incidence of syphilis in this community was quite high at the time but I never felt that Dr. Blank's

success and status in that community was principally due to the "scientific" effectiveness of the pharmacological action of mercury and iodides. I always thought his peculiar usefulness was due to an intuitive understanding of the anxieties and insecurities of his patients and a remarkable ability to reassure and comfort them with the image he created of a sheltering, omnipotent protector. This may not have been scientific but it was excellent medicine for many, many people.

I am sure you know that most of the tons of vitamins, antibiotics, hormones, sedatives or stimulants are not prescribed upon the established scientific basis of need, but rather as part of a program of reassurance and support in much the same way the Witch Doctor rattles bones in a gourd. One uses the tools one has at hand and that are currently in vogue. If one attempted to care for the sick today upon a strict basis of proven scientific fact, it would not be possible to do anything for 95% of those who seek help in a doctor's office.

Modern neurophysiological research is making some fascinating discoveries. It is stimulating and satisfying to read of discoveries that emotion and behavior can have humoral and neurological correlates. It is very important that this research continue and perhaps eventually the clinician will have tools which can reliably affect some of the symptoms that trouble the patient and thus become part of a program to help him find the effectiveness and confidence he has lost.

I don't believe the practicing clinician can really believe that final answers to problems of man will be found in the test tube, but rather in the careful and scientific study of man himself. It is perfectly reasonable that we should place greater hope on the sciences of man, sociology, anthropology and the new science of communication. These new sciences which are concerned with the highest level of man's integration, the level of interpersonal relations, may be able to give us new tools and techniques that will make many more "good physicians."

IMPLICATIONS OF A LONGITUDINAL STUDY OF CHILD DEVELOPMENT FOR CHILD PSYCHIATRY¹

STELLA CHESS, M.D.,² ALEXANDER THOMAS, M.D.,³
HERBERT G. BIRCH, M.D., Ph.D.,⁴ AND MARGARET HERTZIG, M.D.

In child psychiatry, as in psychiatry as a whole, our primary sources of data have been retrospective. The understanding of the developmental process has been derived from the recall by patients or their families of previous patterns of behavior and experience. The analysis of currently observed behavior and subjective state has been dependent upon such retrospectively obtained material.

The adequacy of the retrospective method may be questioned on two grounds:

1. Even if the information obtained is accurate as history, it provides only a partial and often illusory basis for reconstructing the sequences of forces involved in the evolution of individuality. Although a considerable amount of information has been accumulated with respect to factors underlying the general aspects of age-related responses, little is known about the specific influences that contribute individuality to these response patterns. In short, our understanding of what makes *people* exceeds by far our ability to delineate the forces that make a person.

An illusory confidence in our knowledge of the forces contributing to individual development often accompanies involvement in the psychotherapeutic and psychoanalytic process. Starting with the person as a developmental product, through retrospective analysis we seem to be able to define the logic and dynamics of his individual development, to suggest plausible reasons for his movement along one path rather than another at developmental choice points, and even to feel that this knowledge rather fully accounts for his individuality.

³ Assoc. Prof. Psychiatry, New York University School of Medicine.

⁴ Assn. Aid for Crippled Children.

But, as many serious thinkers have pointed out, this type of retrospectively derived understanding is at best only partial. Thus Freud(12) has stated:

So long as we trace the development (of a mental process) backwards, the connection appears continuous, and we feel we have gained an insight which is completely satisfactory or even exhaustive. But if we proceed the reverse way, if we start from the premises inferred from the analysis and try to follow these up to the final result, then we no longer get the impression of an inevitable sequence of events, which could not have been otherwise determined. We notice at once that there might be another result, and that we might have been just as well able to understand and explain the latter. . . .

2. It is also not possible to accept retrospective data as accurate recall of events and processes. While such accuracy may perhaps be unnecessary for the purposes of psychotherapy,⁵ it is of primary importance for the understanding of the sequential patterns of the psychological evolution of an individual. The inaccuracies of recall by patients in psychiatric treatment has been repeatedly observed. In our own study parents have been asked, after a two year interval, to recall important details of their child's functioning in the first year of life(21). These reports have then been compared with data as to these same functions obtained from the same parents at the time of their occurrence. Significant distortions of accuracy have been found as a frequent phenomenon. The distortions have a cultural as well as an individual basis. Thus 15% of the mothers who had never used a pacifier stated they had, and only 6% who had used it failed to recall this. Twenty-eight per cent whose children had sucked their thumbs stated that this had

⁵ Thus Freud, after he discovered that patient reports of various childhood experiences were grossly inaccurate, could still use these distortions effectively for psychoanalytic clinical purposes.

not happened and no parent in 100 recalled thumb-sucking when it had not previously been reported. This opposite direction of distortion corresponds, moreover, to the attitude of the most widely-accepted authority on child-care for this group, who approves of the use of a pacifier, but frowns on thumb-sucking (22). The pattern of distortion in recall is one which causes uniqueness in individual functioning to disappear and to produce information which approximates the socially acquired concept of optimal functioning. These results are in accord with the findings of Gildea (14).

Therefore, on theoretical grounds and for the practical reasons of personal distortion and of social levelling, retrospective data are insufficiently powerful for the delineation of the processes involved in the development of individuality. These factors underlie the marked increase of interest in longitudinal, anterospectively oriented studies of child development in recent years (6, 17, 24). It is evident that only such anterospective and longitudinal investigations can provide the data from which a more definitive theory of individual psychological development may be derived.

However, agreement as to the necessity and desirability of longitudinal study does not automatically lead to the formulation and conduct of a productive investigation. Many such studies have been attempted, but the general result, as described by a recent exhaustive survey of the literature by Stone and Onque, has been the accumulation of "incredible amounts of data which defy any degree of organized analysis and have no relation to a specific, experimentally posed hypothesis. Much of this research, therefore, never reaches the manuscript stage; and if it does, it is formulated as impressions of the author or as case histories" (25). An adequate longitudinal study, in addition to posing a specified and testable hypothesis, must deal with various problems and difficulties; namely: 1. Are the samples of behavior studied characteristic of the individual child? 2. Are the primary data, upon which all subsequent analysis and correlations are based, objective and descriptive, or admixed with interpretations based on some *a priori* theoretical scheme? 3. Are the findings accurate and replicable

by other workers? 4. Are the variables observed and studied pertinent to the problem under consideration? 5. Are the methods of gathering and analyzing data economical, so that a large number of children can be followed? and 6. Are any artificial elements introduced into the data collecting and the observational setting which will produce significant distortion of the characteristics of the child's behavior?

In recent years, a number of studies have been strongly influenced by the formulations of psychoanalytic theory, which offer a systematic and comprehensive theoretical framework for the understanding of the genesis and dynamics of personality development. Unfortunately, these studies have tended to introduce two additional difficulties beyond those enumerated above. First, there has been a tendency to assume that the body of psychoanalytic concepts has already been validated and proven, thus justifying the immediate translation of observed behavioral phenomena into interpretations regarding instinctual tension states (11), strength of oral drive (18), resolution of the Oedipus complex (7), etc. Secondly as Escalona (8), has also pointed out, various theoretic hypotheses based on psychoanalytic concepts have been used as the basis for developmental studies, when such concepts were not definable and testable in experimental terms.

With these issues in mind, our longitudinal study started from the position that at present no adequate theoretical framework exists which would serve as the basis for a deductive approach to individual child development. Consequently, it was our belief that a useful hypothetical framework could be constructed only on the basis of the inductive analysis of data concerning the details of behavioral functioning in infancy and childhood, particularly as they are manifested in the activities of daily living. Collected longitudinally, such data also provide information on the evolution in time of adaptive response patterns. To accomplish this objective, it was necessary to obtain a stable population of infants and to develop an economical method for the continual collection of valid and representative data.

Using a structured interview which fo-

cuses on gathering information on a descriptive, factual level, we have found that it is possible to utilize the parents as a rich source of meaningful, accurate ongoing data on the child's behavior. The parental reports have correlated closely with descriptions of behavior obtained by independent, direct observations. They have also been broad and detailed enough to permit content analysis (26).

The use of the parent as a source of longitudinal behavior data presents several advantages. It permits the gathering of detailed information not only as to the child's single reaction to a particular stimulus such as the bath, a new food or an illness, but also as to the sequence of development of his responses to these same stimuli on repeated exposure. Such data could otherwise only be obtained by an observer actually living in the home. Information from the parent can also be obtained at low investigative cost and thus permits the longitudinal analysis of large samples of children.

Starting with the use of detailed parental interviews as a first source of behavioral information, 110 children have been and are continuing to be followed in a longitudinal study of child development started in March, 1956. The structured interviews with the parents, at 3 month intervals for the first year and 6 month intervals thereafter, in which detailed information is gathered as to the behavior of the child in the various functional activities of daily life, as well as the sequences of reactions to any special situations that arise, have been supplemented by: 1. Periods of direct observation at one or more points during infancy in most of the children, 2. Detailed observation of each child's behavior during a standard play and psychological test situation at three years of life, 3. Direct observation of the child's behavior in nursery school and interviews with the teacher as to the details of the child's functioning at school, and, 4. Structured interview with each mother and father designed to elicit information on parental attitudes and child-care practices.

The prime goal of the study has been to study the phenomenon of individuality in the characteristics of reactivity in the young infant, the consistency, stability and per-

sistence of these characteristics as the child grows older, and their significance for psychological development. Various aspects of the methodology developed for the study and a number of the findings thus far obtained have been reported previously (5, 26).

PRIMARY REACTION TYPES

Early in the study, the content analysis of the parental interviews and of independently obtained direct observational protocols permitted the delineation of individuality in children with respect to 9 features of initial reactivity. In order to permit the continuous study of the significance of these initial characteristics, it was decided to minimize the effect of additional variables such as external environmental influences by making the sample as socially homogeneous as possible. The families in our series, therefore, represent a relatively homogeneous middle-class urban and suburban group with the majority involved in various professional occupations. The child-care practices are generally permissive, with an emphasis directed toward satisfying the needs of the child. In many of the families, fathers participate actively in the care of the child.

The characteristics of reactivity defined initially have been found to be reliably present in the entire study population and can be scored quantitatively on a 3-point scale in each child in each protocol as early as the third month of life. The method of scoring, the evidence for its reliability, and the description of categories have been detailed in previous reports. The 9 categories are:

1. Activity-Passivity refers to the magnitude of the motor component present in a given child's function and to his diurnal proportion of active and inactive periods. Therefore, protocol data on motility during bathing, eating, playing, dressing and handling as well as information concerning the sleep-wake cycle, reaching, crawling, walking, eating and play patterns are used in scoring for this functional category.

2. Regular-Irregular refers to the predictability and rhythmicity or unpredictability and arrhythmicity of functions and can be analyzed in relation to sleep-wake cycle, hunger,

elimination, appetite and demand cycles.

3. Intense-Mild refers to the quality of response and its vigor, independent of its direction. A negative response may be either mild or intense as can a positive response. Responses to stimuli, to pre-elimination tension, to hunger, to repletion, to new foods, to attempts at control, to restraint, to dressing and diapering all provide scorable items for this category.

4. Approach-Withdrawal represents a category of responses to new things, be they people, foods or toys. In it the behaviors reported are scored for the nature of initial responses.

5. Adaptive-Nonadaptive again refers to responses to new or altered situations. However, in this category one is not concerned with the nature of the initial responses, but with the ease with which responses are modified in desired directions.

6. High Threshold-Low Threshold is an omnibus category in which sub-categories are concerned with (a) sensory threshold, (b) responses to environmental objects, and (c) social responsiveness.

7. Positive Mood-Negative Mood represents a category in which overall expression of pleasure-pain, joy-crying, friendliness-unfriendliness are rated.

8. Selectivity-Nonselectivity refers to initial discriminativeness, to clear definition of functions and to the difficulty with which an established direction of functioning can be altered. It is a composite of persistence and attention span.

9. Distractibility-Nondistractibility refers to the ease with which new peripheral stimuli can divert the child from an ongoing activity.

In 95 of the children the parental interview data have already been scored through the first two years of life. In the 45 oldest of these children scoring has proceeded through the third year and into the fourth. In all cases the original definition of the child's reactions on the scale for each category shows consistency and stability at better than the .01 level of confidence. Various clusters of the 9 categories are also discernible. The most frequent one defines a child who exhibits medium or high activity, regularity, adaptiveness, approaching, mild intensity, low threshold, positive mood, distractibility and persistence. Eighteen per cent of the children fall into this cluster, and 26% more show it except for a deviation in only one of any of the 9 categories. At

the other extreme are those children, comprising 7% of the total, who show the characteristics of irregularity, withdrawal, non-adaptability, intense responses, negative mood and non-distractibility. Other types of clustering are also evident, and involve varying numbers of the children.

Each child also appears to have a characteristic mode of response to new situations, which shows consistency even in the increasingly complex situations that appear as the child grows older. The mode of response appears to be compounded from elements involving a number of the basic 9 categories of reactivity. However, we have not yet fully explored the relation of such modes to primary reactivity.

We have labeled our 9 categories of reactivity as primary because they are evident early in extra-uterine life. We have called them reaction patterns and not behavioral patterns, because the individuality and consistency of each child is expressed in a specific reactivity to stimuli, and not in any fixed content of behavior. The behavior content keeps changing as the child grows and matures, but the formal pattern of reactivity tends to remain constant. The etiological question, as to whether the primary characteristics are produced by hereditary, prenatal or neonatal and early postnatal forces, or some combination of these, cannot be determined from our present data, and will require special studies for its elucidation.

The determination of the existence of the primary reaction pattern in the infant bears significantly on one of the basic unresolved problems in child psychology, that of individuality. There has been, on the one hand, increasing recognition of the existence of individual differences in functioning of the young infant, and, on the other hand, an awareness of how little factual data there are regarding this phenomenon (9, 13, 20, 28). Various studies have reported observations on individuality in patterning in specific discrete areas, such as motility (13), perception (2), sleeping and feeding (10), emotional tone (17), autonomic functioning (3), biochemical characteristics (30) and electroencephalographic patterns (29). Our study has attempted a systematic, more behaviorally oriented approach to the ques-

tion of what characterizes individuality in the young child, with results which appear promising for future investigation.

One question arises directly as soon as it is clear that individuality in reaction characteristics is a reliable and persistent feature of child development. What is the relevance, if any, of the primary reactivity characteristics to more complex features of adaptive psychological functioning? In contrast to many previous formulations of constitutional typology, we do not believe that there is any one-to-one correlation between the primary reaction pattern and the specific character of the personality structure that develops in each child. Similarly, there is also no one-to-one correlation between parental practices and attitudes or other specific environmental influences and the course of the child's psychological development (4, 16, 19, 23). Personality structure appears to emerge out of the interplay and interaction of the various forces involved in psychological development. As will be indicated below, our data regarding adaptive functions in the 3-4 year old age group indicate that psychological organization may be the resultant of a highly complex set of interactions in which primary reactivity functions as a significant variable.

In the field of child-care practices, the same lack of any one-to-one correlation between specific practice and resultant effect is also evident (5). Different children appear to respond differently to the same approach of the parent as regards sleeping, feeding, toilet-training or general discipline. A similar practice, such as demand feeding, may result in an irregular schedule in one child and such a regular one in another as to appear at first glance to be the consequence of a rigid clock-scheduled approach.

As previously reported, our data indicate that individuality in the response of different children to parental child-care practices is related to characteristics of the primary reaction pattern as well as to the manner in which the parents apply these practices (5). The primary categories of adaptability, approach-withdrawal, intensity, distractibility and persistence appear especially relevant. The child's general activity level may also influence the response to overall training and discipline. The extremes appear to be

represented by the hyperactive child who is very difficult to restrain and to teach various prohibitions and the quiet, slowly moving child who requires high level stimulation before he approaches the average levels of activation.

In the course of a consultation practice in child psychiatry, one of us (S. C.) has found the concept of primary reaction patterns to be extremely useful in a number of ways. It has helped to avoid the error of assuming that all behavioral phenomena necessarily have a primarily psychodynamic basis. For example, although frequent intense negative responses in a youngster may be an indication of underlying hostility and anxiety, it may also occur as an expression of characteristics of primary reactivity. In advising parents as to the optimal approach to a child, it has frequently been important to distinguish between those undesirable characteristics which are largely psychodynamic in origin and therefore capable of basic change, and those attributes, such as irregularity and withdrawal responses, which are aspects of the primary reaction pattern and are not readily subject to change. In the latter case, although the pattern may not be changed, the parents can be guided to understand the child so that they may function in such ways that the undesirable behavior is minimized by channeling activities as much as possible in constructive directions. For example, there is the child who tends to retreat initially from new experiences with an intense expression of negative mood. If the parents can become aware that this behavior is not a result of motivated negativism, underlying insecurity, or psychodynamically initiated hostility, they themselves can better maintain objectivity and consistency in their handling of the reaction. If they anticipate that the child will have a minor tantrum in each new situation which may be embarrassing for them, but will wear itself out and then may be replaced by tentative positive overtures, they can learn to wait out each such event without complicating it by their own subjective reaction. If, on the other hand, they react with anger, by attempting to coax the child into premature contact or try to persuade him to express a positive mood, they may precipitate a de-

• fensive negativism and hostility and cause the child to be anticipatorily more insecure when approaching new experiences. With patient parental approach such a child can learn eventually that, although he may be initially disturbed by new experiences, if he gives himself time the first response will pass. He will then be able to explore the situation with ease and even with pleasure.

• Even in clear-cut neurotic behavior disorders, it is not infrequently apparent that the disturbed functioning represents an accentuation and distortion of characteristics of primary reactivity to the point of caricature. For example, there are many cases in which the parents respond with growing annoyance and pressure to the manifestation of initial negative mood and withdrawal in the type of child described above. The child's response of negativism and increased negative mood to these parental attitudes can produce a vicious cycle which can finally lead to defensive hostility with constant projections of derogation and aggression. Thus we may obtain as an end product an individual with motivated aggressive and hostile behavior who shows a highly suspicious reaction to anything new, be it a person, place or activity. He makes contact by attacking and assumes that every personal contact must involve an overt or hidden antagonism on the other person's part. In such a case the goal of treatment is to correct this caricature, not to transform the basic pattern. Finally, the knowledge that certain characteristics of their child's behavior are not primarily due to parental malfunctioning has proven helpful to many parents in assuaging feelings of guilt resulting from their assumption of responsibility for all undesirable aspects of their child's behavior.

ADAPTIVE PATTERNS IN THE PRESCHOOL CHILD

In studying the 3 to 5 year age range we have continued to be guided by the principle of recording objective, descriptive items of behavior and avoiding all inferences as to the inner, subjective state of the child at the level of data gathering. Increasingly complex patterns of psychological organization and of interaction with the environment at this age, as well as the development and use of language, make for both

expanded opportunities and increased difficulty in the study of individual characteristics of behavioral functioning. However, our methods are continuing to provide rich sources of behavioral data which are amenable to content analysis. The original 9 categories of reactivity remain scorable and continue to show consistency and stability. New categories of more complex adaptive patterns are being delineated from the behavioral data. These new categories include mechanisms of problem-solving, reactions to success and failure, patterns of social relatedness, type of approach to a new situation, degree and character of independence, degree of influence of immediate environmental stimulus on ongoing activity, and patterns of language utilization. These phenomena also serve to characterize individuality in functioning. These functions, which we have tentatively labeled adaptive patterns, resemble some of the categories which have been called ego functions(15). Our overall methodological approach appears to offer a basis for a reliable, replicable and systematic study of these functions, just as it has proven satisfactory for the study of the simpler behavioral activities of the infant.

Although the analysis of the data is still at a preliminary stage, it appears clear that parental attitudes and practices as well as other environmental factors are very much involved together with the primary reaction pattern in determining the characteristics of the child's adaptive functions. It has also begun to become apparent that any adaptive pattern must itself be analyzed not only with respect to its content and organization, but also as to its temperamental component. There is the suggestion in the data that additional primary patterns may emerge in the pre-school period and play a part in influencing the individuality of adaptation.

WEANING, TOILET-TRAINING AND OTHER EVENTS

The anterospective approach and longitudinal character of the behavioral data in this study have made it possible to analyze the child's reaction to features of important environmental change or influence, such as weaning, toilet-training, the birth of a

younger sibling, and the return of the mother to full-time outside work. These circumstances provide experiments in nature for the exploration of individual adaptive reactions. Viewed from another perspective, these data also provide the opportunity to test the correctness of these formulations which assume that such events are necessarily traumatic because they involve the frustration of one or another hypothetical instinctual drive.

In exploring this auxiliary question, we have made a detailed analysis of the reactions to weaning and toilet training in 50 of the children. Disturbances in behavior coincident or immediately subsequent to these events were considered as relevant even if they involved other aspects of functioning, such as sleeping, motor activity, or social interaction. About 40% of the children were breast-fed and reactions to weaning from either or both breast and bottle were considered. Only one disturbance in response to weaning and only one, in the same child, in response to toilet-training have been found in any of the children. Of special interest is the fact that a number of the children initiated weaning or toilet-training themselves, by refusing to take the bottle and by demanding to be toiletied. In these cases the mothers sometimes resisted the child's desire because of all they had heard and read as to the dangers of early weaning and toilet-training. Instead of the more usually reported syndrome of the mother pressuring the resistant child to be weaned and toilet-trained, we have the very opposite.

In 20 of the children we have had the opportunity to follow the sequences of reaction to the birth and entry into the family group of a younger sibling. The responses of different children have shown the widest possible spectrum of individuality. Reactions have ranged from severe, prolonged disturbance, to mild transient disturbance, to neutral responses, and even to positive socially stimulated reactions.

Six mothers have returned to full-time outside work within a few months after the birth of the child. In 5 cases, the children, who are now 3 to 4 years old, have shown no evidence of disturbance. In the sixth there have been behavioral difficulties

which appear to be associated with special circumstances involved in this situation.

These findings indicate that any categorical formulations as to the psychic dangers inherent in the processes of weaning, toilet-training, the birth of a sibling or the return of the mother to work, are not valid.

SUMMARY AND CONCLUSION

The present paper has described the considerations that led to the formulation of a longitudinal study of child development. It has indicated that such study is necessary for : 1. The determination of the variables which contribute to personality formation, 2. The understanding of individuality in psychological functioning, 3. The relationship of behavioral disturbance to psychodynamic and non-psychodynamic etiologies, and 4. The importance of longitudinal study of a child for parental guidance.

The data presented have demonstrated the existence of stable, primary patterns of reactivity in children. These data were derived from parental interview and a variety of independent direct observational and interview sources. The primary patterns defined have been considered with respect to their early appearance in infancy, their persistence in childhood, and their pertinence for the emergence of adaptive patterns in children. It has been concluded that initial primary reactivity is a crucial variable together with environmental influences in shaping both personality structure and temperament.

THE JUVENILE LEGISLATION IN INDIA ¹

NAUTTAM J. KOTHARI, M.D., D.P.M.²

EXTENT OF PROBLEM

During the period of 1948 to 1954 the number of arrests reported from all 14 states was 86,491. An overwhelming 94.9% went to 10 states and 5.1% to the remaining 4 states. The number of arrests in the States of Andhra, Bombay, Madras and West Bengal comprised 83.3% of that in the whole country. These 4 states are highly industrialized with a marked mobility of the population from rural to urban areas. In Bombay and West Bengal States there is the additional problem of influx of population displaced from Pakistan after the partition.

The Juvenile Legislation. This legislation began in 1850 with federal enactment of the Apprentices Act (Act IXI) to deal with juveniles between the ages of 10 and 18. Under one of the provisions of this Act, a trying magistrate had the authority to bind over boys and girls as apprentices, if convicted of petty offenses or found destitute. The Reformatory School Act of 1876 replaced the Apprentices Act of 1850. The Reformatory School Act of 1897 was an amendment to that of 1876. It provided for establishment of a reformatory institution for delinquent boys under the age of 16. A boy of 14 years of age could get released on license, if there was an arrangement for a suitable employment. This Act did not make provision for juvenile offenders among girls. They were dealt with under the provisions of earlier legislative enactments.

The State of Madras made legislative progress in this field by passing the Madras Children Act (Act IV) in 1920. The State of Bengal followed by passing of the Bengal Act II in 1922. Bombay's Children Act came into effect in 1924. All these legislations have been amended to fulfill the new and growing requirements.

The Madras Act and the Bengal Children Act defined "child" as a person under 14 years of age, a "young person" as one between 14 and 16 years, and a "youthful offender," a person under 16 years of age convicted of an offense punishable with imprisonment. These two states established a Junior Certified School for training of children and Senior Certified Schools for training of youthful offenders.

The Bombay Children Act provides that 1. Only juvenile courts shall deal with the juvenile offenders, 2. There shall be no joint trial of juveniles and adults having jointly committed the same crimes, 3. Juvenile court has the authority to commit a pre-delinquent juvenile to an institution, and 4. To detain him for observation, 5. The exploitation of child employees is punishable, 6. The probation officers are public servants having special privileges and protection in discharge of their duties, 7. The age limit for girls is raised from 16 to 18 years to protect them from danger of seduction or being induced to prostitution.

All but 4 states have enacted suitable juvenile legislation. Under the juvenile laws the age limit for treatment eligibility is 18 years. The Saurashtra Children Act of 1954 has set the age limit up to 18 for the appearance before a juvenile court and up to 21 years for treatment eligibility.

THE JUVENILE COURT SYSTEM

In 1915 a children's court was set up in Calcutta to try offenders under the age of 15. With the passing of special laws, Juvenile Courts were established in Bombay, Calcutta, Hyderabad and Madras.

The states which have special courts or children's courts constituted under special laws are Andhra, Bombay, Jammu and Kashmir, Madras, Mysore and West Bengal. These special courts handle various categories of juveniles and young persons, namely pre-delinquent, delinquent, victimized, socially handicapped and physically and mentally handicapped. The metropolitan areas of Bombay, Calcutta and Hydera-

² Hon. Psychiatrist, Children's Aid Society, Bombay and Visiting Professor in Psychiatry, Columbia University, College of Physicians and Surgeons, N. Y.

bad, have specially appointed stipendary magistrates assisted by one or more honorary magistrates. The Home Department of the State Government makes the appointment of a juvenile court magistrate in consultation with the High Court of Judicature. The controlling authority in respect of juvenile court magistrates in the 3 metropolitan states, is the Chief Justice of the High Court of Judicature. In view of the independent position enjoyed by the judiciary, all courts including special juvenile courts constitute a single hierarchy with the Supreme Court of India at its head.

The juvenile court procedure is characterized by its informality. A few states do not allow advocates or counsels to appear in the juvenile court. Since it is a fundamental right granted by the Constitution to every citizen whether an adult or a child to have adequate legal defense, a counsel

or an advocate for defense may appear in a juvenile court as a matter of right.

METHODS OF TREATMENT OR DISPOSITION BY JUVENILE COURTS

A juvenile court deals with a juvenile or youthful offender in one of the following ways :

1. Restores to parents with or without bond,
2. Restores to parents with or without bond and keeps under supervision,
3. Releases on probation with or without supervision,
4. Commits to an institution for care and protection,
5. Commits to a special juvenile or Borstal Institute for long-term treatment,
6. Commits to an adult institution,
7. Admonishes and discharges,
8. Deals otherwise with any alternative suitable arrangement.

THE IMPACT OF ATARACTIC DRUGS ON A MENTAL HOSPITAL OUTPATIENT CLINIC

MARTIN GROSS, M.D.¹

The Outpatient Department of Springfield State Hospital was started more than 25 years ago as a follow-up treatment of paroled and discharged patients. For many years this department functioned at a leisurely pace. One or two psychiatrists from the hospital spent one afternoon every week in the clinic and saw about 3-4 patients each, a total of perhaps 300 interviews a year. During the fiscal year 1953-54, before the advent of ataractic drugs, there were 312 psychiatric interviews. Since that time, the number of patients who attended the clinic, and the number of psychiatric interviews have increased at an unforeseen pace (Table 1). For the fiscal year 1959-60,

TABLE 1

1954-55	394	1958-59	2686
1955-56	491	1959-60	3420
1956-57	861	(prorated from 10 mos.)	

we estimate a total of over 3,400 psychiatric interviews, more than 10 times as many as in 1953-54. How account for this increase? We are convinced that the main reason is the widespread use of ataractic drugs. In former times many patients came only reluctantly, and we had many cancellations. Today most patients attend the clinic regularly in order to obtain the drugs with which they had been released from the hospital. Formerly, those attending were mainly neurotics, alcoholics, and a few psychotics with specific problems, or whose families brought the patients for a check-

up. There were also epileptics who came for anti-convulsant drugs. At present the majority of the clinic population have had functional psychoses. They have been made aware of the necessity of continued medication in order to be able to continue a more or less normal and useful life in the community. More and more patients are referred to the clinic by their ward physicians upon release from the hospital. More staff members in our hospital are now convinced that chances for survival in the community are far better in those patients who continue to take ataractic drugs than in those who stop doing so.

We have just concluded a two-year, double blind study² on the discontinuation of ataractic drugs in chronic psychotic patients, conducted in the outpatient department, which has given us convincing evidence of the efficacy of such drugs. Patients were divided at random into a control group and an experimental group. The control group was continued under ataractic medication in the form of unidentifiable capsules. In the experimental group, medication was slowly decreased and finally replaced by placebos. Both groups had previously been observed for a preliminary period averaging 4½ months.

Table 2 shows that during the 6 month control period under treatment with active

drugs, 13% of the patients relapsed. On the other hand, 51% who had been under reduced or placebo medication relapsed. Thus, while about 1 patient in 8 relapsed during 6 months under active drugs, about 1 in 2 relapsed in a similar period under reduced medication or placebo. It is noteworthy that 21% relapsed during drug reduction and before they could be started on placebo. Chances for relapse were 3% during the first month after reduction began and rose to a peak of 19% during the seventh month (Graph 1). (Percentage figures for the last quarter of the year may be less valid than for the previous period as the

PATIENTS UNDER OBSERVATION AT THE
BEGINNING OF EACH MONTH

number of patients under observation had shrunk to 16.)

We think that these results can be taken as conclusive evidence of the beneficial action of ataractic drugs on psychotic disorders.

The favorable adjustment in the community of patients under ataractic drugs is demonstrated in Table 3 which shows 4 levels of social adjustment. These figures were obtained from the records of 120 chronic psychotics who had regularly attended the outpatient clinic during the month of January 1959. Alcoholics, psychoneurotics and patients who had experienced only an acute psychotic break or were suffering from organic brain disease are not represented in this group. Thus these figures cannot be applied, without reservation, to the entire clinic population. Nineteen point two percent of these patients were self-supporting or, in the case of women, fully responsible at taking care of their household. Twenty-five percent were seeking work or working intermittently, or, if women, carrying household responsibilities with some help and supervision from relatives or friends. Twenty percent were working in specially arranged and sheltered jobs or, if housewives, functioning as helpers in the home. Thirty-five point eight percent were unemployable, dependent and fully cared for by others.

Table 4 shows that 23 patients of the previously mentioned group of 120 were self-supporting, (three even supported de-

pendents). Seventy-four were supported by their families or lived from pensions or Social Security payments. Only 23 (19.2%) had to depend on public assistance. At the present rate of Department of Public Welfare payments of about \$72 per month, the expenditure from public funds for 23 patients is calculated as roughly \$20,000 per year. That is an average of \$165 per year for these 120 patients. Of course this does not include other Welfare expenses such as medical care, professional services of our Social Service Department, Vocational Rehabilitation, and other agencies, nor does it account for the expenses of running the outpatient department. However, we have estimated the cost of medication on the basis of the total amount of various drugs taken by 235 clinic patients during a single day. The expenditure for ataractic drugs per patient was 16.3c per day or about \$5 per month.

Drug treatment in mental disease, if effective, is certainly the most economic mode of treatment. In our clinic, patients are seen every 2 to 6 weeks and at present there are about 290 active patients. If each of these were to be seen only once a week in a psychotherapeutic interview, the full-time service of 7 psychiatrists would be required, provided that each could treat 8 patients daily. This is economically impossible at present. Our 290 patients are treated by 6 hospital psychiatrists, each of whom spends one day per week in the clinic and treats between 10 and 20 patients. Thus, only one-sixth of the psychiatric manpower is needed.

There are, doubtless, other reasons for the increase in outpatient activity: there is a considerable change in the attitude of the general population, which more and more accepts the responsibility for patients re-

leased from the hospital and placed in the community. There is the cooperation of the general practitioner who, until recently, felt helpless in dealing with psychotic patients. He can now treat the mentally ill in the way he knows best, by prescribing drugs. Then there is the change in the attitude of many psychiatrists. The organically and genetically oriented ones have lost their attitude of hopelessness and many analytically oriented psychiatrists now use drugs in the course of treatment.

Those who minimize the importance of treatment with ataractic drugs as "just another symptomatic therapy" overlook one important factor. For the first time psychotic patients and especially schizophrenics can be stabilized in the community. No doubt the treatment is symptomatic in most cases but so is insulin treatment in diabetes and anti-convulsive treatment in epilepsy. Once the maximum therapeutic result is obtained in the hospital and the maintenance dose of the ataractic drug is determined, a patient can return to his family and sometimes to his job. With continued medication a stable condition can be maintained, perhaps not on the pre-morbid or optimal level but on one which enables the patient to function in occupational, social and family life. Even recurring psychotic symptoms can generally be handled through increased medication. We have seen patients, though periodically hallucinated, cling to their jobs tenaciously and we have helped them with ataractic medication to live through such periods without a social breakdown. Only about 1 in 4 of the relapsed patients had to return to the hospital. Table 5 gives a breakdown of the rehospitalization rates of 108 relapses

TABLE 5
REHOSPITALIZATION

	No. of Patients Relapsed	No. of Patients Returned to Hosp.	Rate of Re-Hospitalization
Patients under active medication	38	19	50%
Patients during drug withdrawal or on placebo	70	9	13%

which occurred during our study. Nineteen out of 38 patients (50%) who relapsed under active medication in the preliminary or control phase had to return to the hospital. Of 70 patients who had relapsed after drugs had been reduced or completely withdrawn, only 9 (13%) needed rehospitalization. The rest were able to continue life

in the community, showing that the previous level of stability can generally be regained under resumed medication. We consider this social stability—never before achieved in the majority of psychotics—as the most important contribution of ataractic drugs to the treatment of patients in an outpatient department.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

COMBINATION DRUG THERAPY IN PSYCHIATRY

JOSEPH A. BARSA, M.D.¹

The use of a combination of drugs in the treatment of mental disorders has been castigated by some as "unscientific" and "shotgun therapy." Such criticism reflects an ignorance of the purpose and actions of psychotropic drugs.

Firstly, psychotropic drugs do not treat mental disorders but rather mental symptoms. The neurotic whose anxieties have been dissipated with tranquilizers still retains his neurotic personality structure with its unhealthy mechanisms; the schizophrenic whose delusions and hallucinations have disappeared through the influence of drugs remains schizophrenic in character structure; the involutional whose depression has been lifted with energizers still has the unhealthy attitudes which permitted the depression to develop. Furthermore, the individual mental patient, neurotic or psychotic, usually presents a multiplicity of symptoms.

Secondly, although psychotropic drugs have been broadly divided into tranquilizers and energizers, the drugs in their respective groups also differ from each other, both in kind and degree of action. It would seem reasonable, therefore, that there might be need for more than one drug to treat effectively the multiple symptoms of the patient. However, combined drug therapy should not be "haphazard therapy," but each drug should be carefully chosen for a particular symptom or constellation of symptoms. Such therapy is best administered by separate tablets for each drug rather than a fixed ratio of drugs in a single tablet.

Thirdly, patients show individual differences not only in their therapeutic response to the same drug, but also in their susceptibility to the development of disturbing side effects. At times, in order to avoid side

effects and still maintain therapeutic potency, it is necessary to combine two or more drugs at lower dosage; e.g., reserpine and chlorpromazine, chlorpromazine and trifluoperazine.

At this point it is important to describe the clinical actions of the drugs. Thus, tranquilizers have two chief clinical actions: a sedative action, and an anti-psychotic (i.e., anti-delusional and anti-hallucinatory) action. Individual tranquilizers contain these actions in varying degrees. Meprobamate and methaminodiazepoxide (Librium) have strong sedative actions, but no detectable anti-psychotic action. Reserpine has strong anti-psychotic action, but relatively weak sedative action.

Phenothiazine derivatives are best divided into three groups, according to both chemical structure and clinical actions. There is the *di-methyl group*: chlorpromazine (Thorazine), promazine (Sparine), triflupromazine (Vesprin); the *piperazine group*: prochlorperazine (Compazine), thiopropazate (Dartal), trifluoperazine (Stelazine), perphenazine (Trilafon), fluphenazine (Prolixin); and the *piperidine group*: mepazine (Pacatal) and thioridazine (Mellaril). According to their sedative strength, we have the di-methyl group, the piperidine group, and the piperazine group. However, in the order of their anti-psychotic effectiveness, they are: the piperazine group, the di-methyl group, and the piperidine group. The piperazine group has the greatest incidence of extra-pyramidal side effects, especially akathisia; next comes the di-methyl group with predominantly Parkinsonian symptoms, and, finally, the piperidine group.

Psychic energizers have three main actions: a stimulating action, an anti-depressant action (separate from the stimulating action), and an anti-psychotic action. Each

¹ Rockland State Hospital, Orangeburg, N. Y.

drug will show these actions to varying degrees. Thus, amphetamine derivatives have only a strong stimulating action. Monamine oxidase inhibitors, which include iproniazid (Marsilid), phenelzine (Nardil), nialamide (Niamid), pheniprazine (Catron) and isocarboxazide (Marplan), have a weaker stimulating action, a strong anti-depressant action, and no anti-psychotic action (indeed, they may cause acute exacerbation of the schizophrenic psychosis). Imipramine hydrochloride (Tofranil) has a still weaker stimulating action, but an equally strong anti-depressant action, no anti-psychotic action, and it, too, can exacerbate a schizophrenic reaction, though to a lesser extent.

Deanol (Deaner) has weak stimulating action, no anti-depressant action, and mild anti-psychotic action. Deprol, a combination of meprobamate and benactyzine, has strong sedative action, mild anti-depressant action, no anti-psychotic action.

In summary, psychotropic drugs treat symptoms only. Since the symptoms of mental disorders are multiple, and since the individual drugs differ in their clinical actions, it may be necessary to use a combination of drugs. Effective therapy, therefore, requires a thorough knowledge not only of the patient's symptoms but also of the clinical actions of the drugs.

REVISED SURVEY OF SELECTED PSYCHOPHARMACOLOGICAL AGENTS¹

JAMES P. CATTELL, M.D.² and SIDNEY MALITZ, M.D.³

Each drug is listed as follows: chemical (generic) name, rating (see below), registered name and manufacturer, range of daily dosage for ambulatory patients, side effects and general comments.

Rating Scale: Each drug is rated according to the following system:

Effectuality:	Toxicity and Side Reactions:
Good—1	Mild—A
Fair—2	Moderate—B
Poor—3	Marked—C

Thus, an effectual drug with minimal toxicity and side effects is designated: 1A; an ineffectual drug with marked side effects or toxicity: 3C

I. The Major Tranquilizers (used primarily for psychomotor agitation and severe anxiety and may decrease hallucinations and delusions).

A. Phenothiazine Derivatives

1. Amino-propyl side chain group.

Chlorpromazine, 1B, (Thorazine-Smith, Kline and French), 25-150 mg. q.i.d. Jaundice, liver damage, agranulocytosis, thrombocytopenia,

urticaria, contact dermatitis, photosensitivity, edema of the extremities, GI syndrome, Parkinsonism, akathisia, convulsive seizures, depersonalization, depression, hypotension, drowsiness, fatigue and cataleptic seizures reported. Possibility of liver damage and increased liability to thrombosis and embolism warrants greatest caution. Seizures following abrupt withdrawal reported.

Promazine, 2B, (Sparine-Wyeth), 50-200 mg. t.i.d. Same side effects as chlorpromazine. Less photosensitivity and jaundice but higher incidence of seizures.

Methoxypromazine, 3B, (Tentone-Lederle), 10-50 mg. q.i.d. Same side effects as chlorpromazine but apparently less chance of liver damage and agranulocytosis.

Trifluorpromazine, 2B, (Vesprin-Squibb), 10-30 mg. t.i.d. More potent and perhaps more rapid acting than chlorpromazine, with essentially the same side effects. Higher incidence of extrapyramidal symptoms; jaundice reportedly rare and only one agranulocytosis on record.

2. Piperidine ring side-chain group.

Mepazine, 3C, (Pacatal-Warner-Chilcott), 25-50 mg. t.i.d. Same side effects as chlorpromazine but

¹ Based on literature available about each drug as of June, 1960 and experiences at the Columbia-Presbyterian Medical Center.

² Assistant Clinical Professor of Psychiatry, College of Physicians and Surgeons, Columbia University.

³ Acting Chief of Psychiatric Research, N. Y. State Psychiatric Institute.

lower incidence of extrapyramidal symptoms and skin reactions. Possibly more agranulocytosis, seizures and atropine-like action. Regarded by some as ineffectual and too toxic for general use.

Thioridazine HCl, 2A, (Mellaril-Sandoz), 25-150 mg. t.i.d. Fewer side effects reported than with other phenothiazines but further studies needed. Leucopenic tendencies (reversible?), thrombocytopenia, galactorrhea, skin reactions reported. Hypotension, extrapyramidal symptoms, edema and photosensitization rare. Hepatic symptoms not reported.

3. Piperazine ring side-chain group.

Prochlorperazine, 2B, (Compazine-Smith, Kline and French), 5-15 mg. t.i.d. Fewer side effects than chlorpromazine but higher incidence of extrapyramidal symptoms. One report of spasm and glottis edema requiring tracheotomy. Jaundice and agranulocytosis not reported.

Perphenazine, 1-2B, (Trilafon-Schering), 2-16 mg. t.i.d. Fewer side effects than chlorpromazine, notably less drowsiness and absence of agranulocytosis, liver impairment and photosensitivity. Higher incidence of akathisia and dyskinetic syndrome. Convulsive seizures, cataleptic attacks in children, galactorrhea, angioneurotic edema, ankle edema, reduced appetite, GI disturbances and urinary urgency and incontinence have been reported.

Thiopropazate, 2B, (Dartal-Searle), 2-10 mg. t.i.d. Parkinsonism, akathisia and dyskinetic syndrome more prominent than with chlorpromazine. Jaundice and leucopenia not reported. Otherwise, comparable to chlorpromazine.

Trifluoperazine, 2B, (Stelazine-Smith, Kline and French), 1-5 mg. t.i.d. Fewer side effects than chlorpromazine. Parkinsonism, akathisia, dyskinetic syndrome, agitation and turbulence prominent. Occasionally may intensify psychotic symptoms. No reports of jaundice or agranulocytosis. Does not produce drowsiness. Hypotension, blurred vision, dryness of mouth and transient

macular eruption have been noted. Fluphenazine, 2B, (Permitil-White; Prolixin, Squibb), 1-10 mg. daily initially; 1-5 mg. daily for maintenance. (White recommends only 0.5-1 mg. daily.) Extrapyramidal signs and symptoms common. Leucopenia reported in 4 patients thus far. Marked hypotension resulting in neurocirculatory collapse has occurred in a few patients. No reports of jaundice or photosensitivity and skin reactions are rare. Blurred vision, dizziness, edema, nasal congestion, polyuria, perspiration, flushing, lethargy, depression, weakness, numbness, nausea, vomiting, constipation, diarrhea, weight gain and loss, anorexia, dry cough and convulsions reported as occurring occasionally. Least sedative effect of the phenothiazines. Special caution and lower dosage required in treating older patients.

B. Rauwolfia Alkaloids

Reserpine, 2-3B, (Serpasil-Ciba; Reserpoid-Upjohn), 0.5-1 mg. b.i.d. Jaundice and agranulocytosis not reported. Skin reactions, Parkinsonism, akathisia, dyskinetic syndrome, seizures, depression with suicidal ideation, depersonalization, hypotension, drowsiness, fatigue, excitement, edema and rupture of peptic ulcer reported.

Deserpidine, Canescine, Recanescine, 3B, (Harmonyl-Abbott), 0.24-2 mg. t.i.d. Fewer side effects claimed than reserpine.

Rescinnamine, 3B, (Moderil-Pfizer), 0.25-0.5 mg. b.i.d. Fewer side effects than reserpine.

Rauwolfia serpentina, whole root, 3A, (Raudixin-Squibb), 100-300 mg. daily. Fewest side effects of Rauwolfia group.

Rauwolfia serp., alseroxylon fraction, 3B, (Rauwiloid-Riker), 4 mg. daily. Fewer side effects than reserpine.

Medication to Prevent Drug-Induced, Extrapyramidal Syndrome.

Ethopropazine (Parsidol-Warner-Chilcott), 10-50 mg. q.i.d.

Biperiden (Akineton-Knoll) 2 mg. 1-3 times a day.

Trilixyphenidyl (Artane-Lederle) 2 mg. t.i.d.

Methanesulfonate (Cogentin-Merck

Sharp and Dohme) 1-4 mg. 1-2 times a day.

Procyclidine (Kemadrin-Burroughs-Wellcome) 2.5-5.0 mg. 3-4 times a day. Side effects that may appear with most of these: Dryness of mouth, blurring of vision. Giddiness, excitement, muscle weakness with high doses. Delusions and hallucinations with high doses in elderly patients. Caution in patients with glaucoma, tachycardia, prostatic hypertrophy (e.g., when parasympathetic inhibition is undesirable).

Medication for Hypotension with Neurocirculatory Collapse:

Levarterenol bitartrate (Levophed-Winthrop). Administered i.v. in 5% dextrose solution. (Epinephrine is contraindicated; may lower blood pressure further.)

II. The Minor Tranquilizers (for anxiety-tension states).

A. The Substituted Propanediol Group

Meprobamate, 2B, (Miltown-Wallace; Equanil-Wyeth); 200-400 mg. t.i.d. No convincing studies demonstrating superiority to barbiturates. Meprobamate medication may be associated with production of fever, malaise, nausea, vomiting, headache, increased peristalsis, cardiac dysrhythmia, hypotension with shock, skin rashes, angio-neurotic edema, a non-thrombocytopenic purpura, temporary leucopenia, itching, drowsiness, euphoria, restlessness, hypomanic conditions, diplopia and coma. Addiction reportedly widespread. Withdrawal syndromes may be severe, including convulsions with abrupt withdrawal. Potentiates alcohol, barbiturates and antihistamines.

Phenaglycodol, 3A, (Ultran-Lilly), 300 mg. t.i.d. Said to allay anxiety without dulling mental acuity or awareness. Further data needed.

B. Diphenyl Methane Derivatives

Azacyclonal, 3A, (Frenquel-Merrell), 200-400 mg. daily. Introduced as an anti-hallucination and anti-confusion drug. Value not confirmed.

Benactyzine, 3B, (Suavitil-Merck), 1-3 mg. daily. Contraindicated in "hostile" patients. May produce concentration difficulty, deperson-

alization, paresthesias, muscle weakness, dizziness, tension, nausea, vomiting, dry mouth, diarrhea, ataxia, palpitation, apathy, indifference. Recently combined with meprobamate (Deprol-Wallace) as an antidepressant-rating: 3B.

Hydroxyzine HCl, 3A, (Atarax-Roerig), 10 mg. t.i.d. Of questionable value except in very mild anxiety. No side effects yet reported.

Hydroxyzine pamoate, 2A, (Vistaril-Pfizer), 25-100 mg. t.i.d. Various reports of effectuality in every psychiatric syndrome and in almost every specialty of medicine. Minimal side effects.

Phenyltoloxamine, 3B, (PRN-Bristol), 50-200 mg. b.i.d.-q.i.d. Formerly *Bristamin*, a non-prescription antihistamine, 1951-57. Now recommended for anxiety states and certain psychosomatic disorders. Drowsiness, nausea, tachycardia and dryness of mouth reported.

Pipethanate, 2-3A (?), (Sycotol-Reed & Carnick), 3-6 mg. t.i.d. Drowsiness. More data needed.

C. Other Minor Tranquilizers

Aminophenylpyridone, 2-3B (?), (Dornwal-Wallace & Tiernan), 200-400 mg. t.i.d. Drowsiness, dryness of mouth, vertigo, nausea, blurred vision, stimulation, pruritis. More data needed.

Methaminodiazepoxide, 2B (?), (Librium-Roche), 10-20 mg. t.i.d. Occasional drowsiness (frequent in dosages over 50 mg./day). Paradoxical stimulating effect reported. Cumulative effect heralded by drowsiness. More data needed.

III. Anti-Depressives

A. The Hydrazines

Iproniazid, 2C, (Marsilid-Roche), 50 mg. daily in divided doses—reduced to 10-30 mg./day. Most effectual at 150 mg./day, but toxic effects may appear at doses above 50 mg./day. U. S. Dept. HEW has reported 180 cases of hepatitis, with 20% fatalities. Side effects: dizziness, ataxia, loss of muscular tonus, hypotension, accommodation disturbances, headache, dry mouth, flushing, sweating, euphoria, confusion, restlessness, depression, constipation, delay in starting urina-

tion and reversible hypochromic anemia. Edema, dyspnea, cardiac failure and neuralgic pain also reported. Potentiates alcohol, ether, barbiturates, meperidine, cocaine, procaine and phenylephrine. Patients receiving iproniazid should be given the entire vitamin-B complex concomitantly.

Pheniprazine, 1-2 B, (Catron-Lake-side), 12-3 mg. daily (initial and maintenance doses). Hypotension, red-green visual defect, mouth dryness, ankle edema, blurred vision, drug rash, constipation, delayed micturition. At least one fatal jaundice reported. List of drugs Catron potentiates is not yet complete. Watch for neurological syndrome with tremors, muscle rigidity and difficulty in locomotion. Further data needed.

Isocarboxazid, 2B, (Marplan-Roche), 30 mg./day initially with reduction to 10-20 mg. or less for maintenance dosage. Side effects essentially those of iproniazid except no evidence of liver damage reported yet. Overactivity, jitteriness, insomnia, hallucinations may occur in excited patients on higher doses. Contraindicated in epileptics until further studies completed. More data needed.

Phenelzine, 2B, (Nardil-Warner-Chilcott), 15 mg. t.i.d.—15 mg./day. Hypotension, nausea, ankle edema, delayed micturition, constipation, insomnia, drug rash, restlessness, headache, dizziness, heartburn. 50% of patients showed abnormalities in liver function tests in one report. Further data needed.

Nialamide, 2-3B, (Niamid-Pfizer), 50-200 mg./day—initial, and 12-25/day—maintenance. Essentially same side effects as other hydrazines. Liver involvement not reported (P). More data needed.

B. The Amphetamines

Dextroamphetamine, 2B, (Dexedrine—Smith, Kline and French), 2.5-10 mg. t.i.d. Side effects: Anorexia, insomnia, palpitation, anxiety and feeling of being "driven." Non-toxic when used in therapeutic doses under medical supervision. Occasional reports of psychosis and habituation when self-administered

in high doses. Contraindicated in patients with cardiovascular disease.

Dextroamphetamine with amytal, 1-2A, (Dexamyl-Smith, Kline and French), dose: same as above (includes 30 mg. amobarbital per 5 mg. D-amphet.). D-amphetamine side effects minimum or absent if dose is properly adjusted. Effect is to allay anxiety, relieve depression and facilitate integrated functioning. Often neutralizes depersonalization phenomena.

Methamphetamine, 2B, (Desoxyn—Abbott; Methedrine-Burroughs-Wellcome), 2.5-5 mg. t.i.d. Effectuality and side effects lie between dexedrine and dexamyl.

C. Other Anti-Depressives

Deanol, 3B, (Deaner-Riker), 25 mg. t.i.d. The few available reports find this drug useful in depression and schizophrenia. The rating given reflects the impression at the N. Y. State Psychiatric Institute.

Imipramine, 1-2B, (Tofranil-Geigy), 25-50 mg. t.i.d.—with less for maintenance. Two to 30 day lag before significant therapeutic response but majority during first week of medication. Tremor and agitation, nausea and vomiting, dizziness, perspiration, palpitation, dry mouth, constipation, headache, hypokinesia, blurred vision, extrapyramidal signs, difficulty in urination, dermatitis, insomnia, decreased appetite, syncope, photosensitivity, hypotension, edema. Hepatitis and acute myocardial infarction and reversible leucopenia reported. Further data needed.

Methylphenidate HCl, 2B, (Ritalin-Ciba), 5-10 mg. t.i.d. This drug and pipradol reportedly do not produce the unpleasant side effects of the amphetamines. Actually, they do. A shock-like condition may develop with tremor, sweating, tachycardia, headache, vertigo, motor restlessness. Reported to be useful in counteracting the lethargy associated with some tranquilizers.

Pipradol HCl, 3B, (Meratran-Merrill), 1-2.5 mg. t.i.d. May produce insomnia, nausea, skin rash. May aggravate existing anxiety and produce psychotic phenomena.

Said to be contraindicated in patients with anxiety, hyper-excitability, paranoia, agitation and obsessive-compulsive states.

Tranlycypromine, 2A (?), (Parnate-Smith, Kline and French, formerly SKF 385), 10 mg. t.i.d.-b.i.d. A non-hydrazine MAO inhibitor. Hypotension, dizziness, insomnia. More data needed.

IV. Psychotogenic Drugs :

Increasing publicity about hallucinogenic agents and claims that they expedite psychotherapy warrants the inclusion of this group. Many of these drugs contain the indole nucleus and are related to serotonin (5-hydroxytryptamine). Therapeutic effectuality and toxicity rating : 3C.

d-LSD-25 (Lysergic acid diethylamide) (Delysid-Sandoz). An ergot alkaloid with an indole nucleus. Not available commercially in the U. S. but can be prescribed in Great Britain. It is claimed that in repeated doses of 20-70 gamma, the drug will facilitate psychotherapy. In doses exceeding 100 gamma, this is a potent psychotogenic drug that produces visual hallucinations, depersonalization phenomena, autonomic disturbances and fluctuations of affect without impairing the sensorium. Effects usually continue for 8-24 hours and there are occasional instances of more protracted reactions.

O-Phosphoryl-4-hydroxy-N-dimethyl-tryptamine (Psilocybin-Sandoz). A Mexican mushroom derivative with an indole nucleus. Dosages of 6-30 mg. produce psychotic pheno-

mena similar to those seen with d-LSD-25. This is an experimental drug and further data are needed.

JB-329, (Ditrane-Lakeside). A tertiary amine derived from a group of 3-N-substituted piperidyl benzilates. Reported to have hallucinogenic and anti-depressant properties at 10-20 mg. doses. Our experiments indicate that it induces a toxic, confusional psychosis that is qualitatively different from those associated with d-LSD-25, Psilocybin and mescaline, in which the sensorium remains clear.

Mescaline. Has been synthesized as mescaline sulfate but can be obtained from peyotl cactus berries native to southwestern U. S. This experimental drug, in a dosage range of 0.5-0.75 Gm. produces a clinical picture similar to d-LSD-25.

There is no conclusive evidence that these drugs are more effectual in facilitating psychotherapy than such drugs as amobarbital sodium, methamphetamine and other related ones, when combined with psychotherapy. These potent psychotogens can and do release severe psychopathological symptoms in some individuals, including acute dissociated states, depression and self-destructive behavior as well as paranoid syndromes and acutely disturbed and aggressive behavior. Such drugs should be used only in a hospital by psychiatrists familiar with their effects. Adequate facilities and personnel must be available to manage untoward reactions, either physiological or psychopathological.

TRIFLUOPERAZINE : A REPORT OF A CLINICAL TRIAL IN BACK WARD PSYCHOTIC PATIENTS

JOHN A. GUIDO, M.D., AND GEORGE Y. ABE, M.D.¹

Since the introduction of the phenothiazines, clinicians have reported satisfactory symptomatic relief of psychiatric disturbances. Several have supported

the contention that such pharmacological therapy has been more useful in the management of chronically ill patients, yet there still exists the serious problem of accumulation of chronically regressed psychotic patients on the so-called "back ward." Despite the interruption of the regressive

¹ Respectively Senior Psychiatrist, and Associate Superintendent, Metropolitan State Hospital, Norwalk, Calif.

course of their illness, many patients continue to display psychotic mechanisms on examination. In our two months' study we have termed such treated patients as "corrected psychotics," since only their interpersonal adjustment is obviously more appropriate.

Trifluoperazine is a recent phenothiazine derivative which was selected for a study of its effects on a group of 20 "back ward psychotic patients." The following categories were included: 11 chronic undifferentiated schizophrenics, 8 chronic brain syndromes with psychotic reaction, 1 chronic brain syndrome with mental deficiency.

The drug was given in repeated doses throughout the day. Initially, the dose of 2 mgms. t.i.d. was increased after the first week to as high as 30 mgms. b.i.d. depending upon the clinical response. The most suitable dosage in the majority of the cases was approximately 20 mgms. on a b.i.d. schedule. Injectable trifluoperazine was administered in one patient up to 10 mgms. daily in divided doses. Blood pressure readings, urinalysis and hemograms were recorded.

RESULTS

During the first 6 weeks, improvement was noticed in 65% of the patients. Many were eating and sleeping better; others became less destructive, and participated in the ward routine. They complained more of their physical problems such as ingrown toenails, halitosis, dermatoses, wanting haircuts, which before trifluoperazine went seemingly unnoticed by the patient. There were fewer injuries from assaultive behavior, fewer accidental falls, marked reduction of hours in the "short hall" of seclusion; and many took pride in more appropriate grooming. One of the patients, who had "not talked" over the past 10 years, cheerfully asked the attendant on the ward if he could use a broom to help with the work on the ward.

The maximum tolerated dose was 20 to 60 mgms. with the only side effect of pseudo-Parkinsonism, and akathisia, which was noticeable at approximately 40 mgms. in the largest number of patients. The onset

of dyskenetic symptoms was more obvious early if the drug was administered in large doses initially. These were quite readily reversible with an anti-Parkinson drug, or reduction of dosage, and if immediate relief was necessary, intravenous caffeine sodium benzoate was administered.

CONCLUSION

The double blind method would not have been useful in this study because of the frequency of extra-pyramidal side reactions, and the 10-22 year period of hospitalization of the patients with various therapy regimens. Therefore, the patients served as their own controls. It was found that the largest number of patients improved over approximately 6 weeks, and steady improvement was noticeable in the remainder of the patients when the drug was continued. This drug is useful in chronic psychotic patients. There were no noticeable urinary or hematological side effects, or variations in blood pressure.

As compared to the other tranquilizers, trifluoperazine exerted a more appropriate and definitive controlling effect on aberrant behavior. As reported elsewhere, it was found to be noticeably more beneficial in the chronic back ward patients than other phenothiazines and serpentina derivatives; it permitted the utilization of other therapeutic techniques and rehabilitation and re-socialization regimens(1, 2, 3). The Rauwolfias and phenothiazines, alone or in combinations, frequently produced indifference as contrasted to the freely outgoing and attentive behavior produced by trifluoperazine. The seclusion hours were appreciably reduced. The least amount of beneficial effect was in the lobotomized patient. Patients were noticeably motivated toward ward and ancillary therapies. The improvement in all cases described is purely symptomatic. Most of the patients who were actively hallucinated continued to experience these phenomena, although apparently seemed less motivated to act upon them(4).

The drug is found to be worthwhile, and further study is warranted to avoid drawing definite and final conclusions from this simple clinical trial.

ON THE PARENTERAL USE OF AMITRIPTYLINE (ELAVIL—MERCK): A PRELIMINARY REPORT

HERBERT FREED, M.D.¹

Amitriptyline,² a new antidepressant agent has been reported by Dorfman to have clinical effectiveness comparable with the presently available antidepressant drugs. Amitriptyline, 5-(3-dimethylamino-propylidene)-dibenzo [a,d] [1,4] cycloheptadiene hydrochloride, structurally resembles imipramine and shows the same spectrum of pharmacologic activity. Neither of these agents is an amine oxidase inhibitor.

Studies in dogs in which 2 mgm./Kg. was administered intravenously induced a small fall in blood pressure followed immediately by a minor increase in pressure. A larger dose of 4 mgm./Kg. given rapidly produced a transient fall which recovered to normal within 10 minutes. No electrocardiographic changes were observed. Chronic oral administration in animals showed no effect on the cardiovascular system.

In the course of the treatment of over 30 patients with Elavil given orally, it was found that the drug could be administered parenterally both intramuscularly and intravenously without the development of any side effects other than drowsiness when an excessive dose was given. Twenty-three patients ranging in age from 18 to 78 were given Elavil in doses ranging from 10 to 30 mgm. intravenously on 1 to 19 occasions, in office practice and at Roseneath Farms Sanatorium. Significant changes in pulse

rate or blood pressure did not occur nor was postural hypotension observed in these patients. Drowsiness was encountered in the 25 to 30 mgm. dose range. The usual psychophysiological response could be described as a pleasant state of relaxation. In 7 patients there seemed to be increased interest in eating. Parkinsonism or any form of basal ganglia involvement as well as other significant side effects were noteworthy in their absence. It was my impression that this drug acted both as a tranquilizer and as an antidepressant through its influence on the "anxiety factor" in many depressions.

In this series of patients there were two who were depressed, with anorexia and a significant degree of anxiety, who had also suffered with cerebral insults with pyramidal tract signs as well as some evidence of extra pyramidal involvement. Shock treatment which had been used for previous episodes of depression was considered too dangerous now because of evidences of cerebral insufficiency. These patients were given injections of 10 to 15 mgm. intravenously once or twice a day for 12 days along with an oral dose of 50 mgm. b.i.d. The rapid favorable response evidenced by a marked improvement in gait (without significant change in objective neurologic finds) as well as the lessening of anxiety was impressive to the nursing staff and to the doctors. The subsequent intravenous administration in 10 to 15 mgm. doses to 3 elderly patients who were tense and had tremors brought about a response of less-

¹ Medical Tower Bldg., 255 South 17th St., Philadelphia 3, Pa.

² Merck, Sharp & Dohme, Division of Merck & Company, Inc. has assigned the trademark Elavil to amitriptyline.

sening of tension; diminution to removal of tremor (transient) and a more satisfactory interview.

The relatively rapid removal of tension with or without elevation of mood in patients with definite or probable organic pathology in the central nervous system, without the development of disturbing side effects, suggests that this possible indication for the drug be studied by other investigators. From my extended experience with the use of a variety of tranquilizers and

other drugs in the treatment of the elderly patient with tension and/or anxiety there would seem to be very few which are active and yet free of possible serious side effects when given intravenously. The objection that there may not be a great need for the intravenous use of such a drug may be justifiable but one can not deny that it is comforting to have available a drug which can be used safely when a rapid response is desirable.

CLINICAL TRIAL OF METHAMINODIAZEPOXIDE (LIBRIUM)

ROBERT S. WALZER, M.D., MORTON L. KURLAND, M.D., AND
MANFRED BRAUN, M.D.¹

Methaminodiazepoxide (Librium)² was released as a non-phenothiazine tranquilizing agent reportedly beneficial in the therapy of various psychiatric disorders (1, 2, 3).

At the Bronx V.A. Hospital, 74 patients with a variety of diagnoses were selected for a clinical study of this drug. Depending upon the therapeutic response, the drug was given in divided doses of 40 to 300 mg. daily for 6 to 8 weeks. No other chemotherapy was given. A period of 3 to 10 days without chemotherapy, following admission, was allowed for hospital adjustment, spontaneous improvement, and for subsidence of the enthusiasm generated by current publicity of a new wonder drug. Patients were evaluated weekly by a team of doctors, nurses, and occupational therapists. Routine urinalysis, blood count, and alkaline phosphatase were obtained weekly, and the blood pressure was recorded (erect and sitting) twice weekly; the same data had been obtained prior to beginning medication.

Therapeutic effects varied markedly from patient to patient and from ward to ward. Contagious enthusiasm and placebo effect were marked in 24 patients. These individuals were dropped from the study and the evaluation of the drug continued with the remaining 50 patients.

Anxiety was the symptom which responded most consistently to treatment. Twenty-two of 40 patients with this symptom in all diagnostic categories showed marked and sustained reduction of anxiety while on the medication; this improvement was not reproducible by the identical-appearing placebo.

Other symptoms were not affected. In contrast to reports mentioned above, we found no notable improvement in 6 of 9 obsessive-compulsive patients; 3 showed some relief of tension regarding their rituals but no actual change in their behavior occurred. Three of 4 patients with phobic reactions had no relief; 1 showed moderate improvement. Most patients experienced moderate drowsiness during the first week or so.

Laboratory tests revealed no abnormalities, except for reversible eosinophilia of 6 to 9% in 8 patients. Systolic B.P. taken in erect position dropped 10 to 20 mm. mercury in 5 patients on 40 mg. daily, and as much as 40 mm. in 2 patients. This occurred in the first week of therapy and reverted to previous levels within 2 weeks without interruption of medication; some of these patients sensed orthostatic "faintness" without syncope, but others described this sensation with normal B.P.

Interesting incidental findings include hostile and/or aggressive acting out on the part of 4 passive dependent patients; this

¹ From the Psychiatry and Neurology Service, Bronx Veterans Administration Hospital, Bronx, N. Y.

² Product of Hoffmann-La Roche Inc., Nutley, N. J.

aggressive behavior was not related to psychotherapy. Eight patients noted that the drug seemed to render them more sensitive to alcohol, *i.e.*, less alcohol was required to cause intoxication, and 2 patients had episodes of violent destructive behavior suggestive of pathological intoxication. Two disturbed schizophrenics with repeated self inflicted cigarette burns, who did not respond to 1200 mg. of chlorpromazine daily, stopped burning themselves when given 300 mg. of methaminodiazepoxide per day. Patients who suffered from depression were not helped by Librium; however, 5 patients with depression were given the drug in conjunction with EST because of considerable apprehension regarding the treatment. These patients now accepted the treatment and became less apprehensive concerning it. This effect disappeared when the drug was temporarily stopped.

In summary, methaminodiazepoxide was found to be most beneficial in relieving the anxiety arising from anxiety neuroses; its effect on anxiety in other psychiatric conditions was more limited, variable and unpredictable. Its influence on other symptoms was minimal. Patients should be warned of possible lethargy, and of the alcohol-potentiating effect of the drug. Further observation of its usefulness in conjunction with shock therapy is warranted.

THE USE OF FLUPHENAZINE (PROLIXIN) IN REHABILITATION OF CHRONIC SCHIZOPHRENIC PATIENTS

LEON REZNIKOFF, M.D.¹

A group of 50 chronic schizophrenics refractory to ECT and numerous ataractic drugs had been treated for 3 to 4 months with fluphenazine². Patients selected for this study had been uncooperative, withdrawn schizophrenics who had been considered in the past, as hopeless even for institutional adjustment; it had been practically impossible to engage them in any institutional activities. On the average, duration of psychosis was over 12 years. The youngest patient was 17 years old, the oldest 70. There were 42 males and 8 females.

Because of prolonged action of fluphenazine and high potency, the drug was administered only once a day.

The initial dose consisted of 2.5 mg. for some patients and 5 mg. for others; the dose was gradually raised to a maximum of 20 mg. per day. When maximum improvement was achieved, the dose was gradually

reduced to maintenance dose of 2.5 or 5 mg. per day.

Extrapyramidal signs are the most important and frequent side effects of this drug. While most patients began to show extrapyramidal system signs when the drug was raised over 10 mg. per day, there had been a few patients who developed these symptoms on 5 mg. per day, and 16 (32%) did not show extrapyramidal symptoms even after 12 weeks on as large doses as 15 mg. to 20 mg. per day. These were controlled by reducing the dose of fluphenazine and administration of Akineton, Artane or Cogentin.

An interesting beneficial side reaction occurred in one case.

E. C., a 35-year-old schizophrenic woman was also suffering from advanced rheumatoid arthritis; for a year before admission to the mental hospital she spent most of her time in bed because of crippling arthritis; she had been treated with Cortisone, but developed peptic ulcer; treatment of arthritis was then switched to Butazolidin, but it also had to be discontinued because of blood dyscrasia. Mean-

¹ Clinical Director, Hudson County Hospital for Mental Diseases, Secaucus, N. J.

² Fluphenazine was kindly supplied for this study by Squibb and Sons under trade name, Prolixin.

while her condition deteriorated to such degree that she had to be committed to our hospital. She was started here on 5 mg. fluphenazine per day; a week later the dose was increased to 10 mg. per day. Two weeks after treatment was started there was noticed not only marked improvement in her mental condition, but all discomfort and pain from arthritis disappeared. The dose of fluphenazine was gradually reduced to 5 mg. per day and later to 2.5 mg. She was released for convalescent care after 3 months on this therapy.

Blood counts were made at frequent intervals; a few patients had slight leucopenia, but no cases of agranulocytosis, skin rash or jaundice had been observed.

Of the 50 patients treated with fluphenazine, 29 (58%) improved sufficiently to be considered for convalescent care or achieved a fairly good institutional adjust-

ment; 21 patients (42%) showed only slight or no improvement, and therefore classified as unimproved.

SUMMARY AND CONCLUSIONS

1. Fifty chronic schizophrenic patients with an average duration of mental illness of over 12 years and refractory to any other treatment had been treated with fluphenazine for a period of 3 to 4 months.

2. Twenty-nine patients (58%) improved and 21 (42%) remained unimproved.

3. The dose of fluphenazine varied from 2.5 mg. to 20 mg. per day. When the dose of fluphenazine was raised over 10 mg. per day, 50% of patients developed extrapyramidal symptoms.

4. Fluphenazine is a valuable adjunct in the total program of rehabilitation of chronic schizophrenic patients.

CONVULSIONS ASSOCIATED WITH ANTI-DEPRESSANT DRUGS

W. L. SHARP, M.D.¹

Because of increasing interest and usage of the mono-amine oxidase inhibitors, I wish to submit the following 3 case reports of epileptiform seizures occurring following use of these drugs.

Case No. 1.—P.C., age 39, was placed on imipramine (Tofranil—Geigy) 25 mgm. t.i.d. p.c. on 8/3/59. In three days this was increased to 50 mgm. t.i.d. p.c. On 8/15/59 this patient experienced a definitely described grand mal seizure, with total loss of consciousness, amnesia, and jerking of all extremities; witnessed by his wife. Following this grand mal seizure, he was immediately hospitalized and a lumbar puncture done, which was all negative.

Because of the patient's resistive depressive reaction, on 10/5/59, Niamid 25 mgm. t.i.d. p.c. was prescribed. On 10/19/59 he had another grand mal seizure with jerking of all extremities, total unconsciousness, and frothing at the mouth. This medication was promptly stopped and the patient placed on Dilantin 1/10th gm. plus Phenobarb. gr. 1/4th p.c. and h.s. No more seizures were experienced and none has been experienced to date (6/14/60).

On 12/18/59, an EEG was reported as "undoubtedly abnormal and suggesting the

possibility of some temporal lobe dysfunction. No precise localized lesion such as tumor was indicated at that time."

Case No. 2.—E.P., age 35: On 9/10/59, because of a resistive reactive depression neurosis, this patient was placed on phenelzine (Nardil) 15 mgm. t.i.d. By 10/24/59, it was reported that she had had two "fainting spells" with definite losses of consciousness and amnesia. Later, two grand mal seizures with jerking of all extremities and even bruises to patient in falling were reported. The drug was stopped and Dilantin 1/10th gm. t.i.d. p.c. plus Phenobarb. gr. ss p.c. and h.s. were prescribed. An EEG could not be obtained. This patient had never had any type of seizures or spells like this in her past life. She was kept on Dilantin and Phenobarb. until 3/7/60. She has never had any more seizures of any type, to this date (6/14/60).

Case No. 3.—G.M., age 63: This patient had never been known to have any type of losses of consciousness, fainting spells or seizures in his past. Because of his tendency to be a recurrent chronic depressive, he was placed on Niamid 25 mgm. t.i.d., on 9/1/59. By 12/3/59 he had a grand mal spontaneous seizure. Because of the experience of the first

¹ 449 Citizens Bank Bldg., Anderson, Ind.

two cases, Nafmid was immediately stopped. He was given Phenobarb. grs. 1½ at bedtime and two Fiorinal tablets q.4.h., p.r.n. for headaches. This has gradually been discontinued and Librium 10 mgm. t.i.d. has been substituted. No seizures have been reported to date (6/14/60).

All 3 cases had mild auras of crawling, cramp-like sensations ascending through the extremities upward, immediately preceding the seizures.

I have treated a total of 58 cases on three of the mono-amine oxidase inhibitor drugs. All 58 cases were given the therapeutic dosages usually recommended by their respective drug manufacturers.

COMMENT

These major side reactions to these drugs all pose several questions and points :

1. That they may not exactly be "the answer to a general practitioners' prayer" as

some drug manufacturers would have you believe. They are certainly not the full answer to the psychiatrist who might possibly be sued for giving potentially convulsant-inducing drugs to patients, some of whom might be driving a motor vehicle. (A grand mal convulsion could presumably cause more trouble to a car driver than the usual doses of tranquilizers or sedatives given to office patients.)

2. Should these drugs be given at all except to hospitalized patients under complete observation where (a) suicide can be prevented and (b) where they would not be driving a motor vehicle ?

CONCLUSIONS

1. From my results of three cases developing epileptiform seizures, out of 58 cases, which have been on the more commonly used MAO drugs, it would appear that we could expect this unwelcome reaction in about 4 or 5% of cases.

PSYCHIATRIC FACILITIES IN TOKYO AND TEL AVIV, 1958

IRWIN J. KLEIN, M.D.¹

The writer visited Tokyo University in May, 1958, and was cordially received by Professor A. Kimoto. The psychiatric and neurological departments, which are combined, have an outpatient census of about 8,000 annually. They have 40 beds and see both psychiatric as well as neurological cases. From here patients are sent to the Matsuzawa Municipal Psychiatric Hospital which has about a 1,000 bed capacity. Treatment generally has been the same recently (insulin and ECT) even after introduction of drugs (reserpine, chlorpromazine, etc.). Last year they found that the results with new drugs were, generally speaking, the same as with ECT, although the control of patients was easier. Recurrences were about the same as when ECT alone was given.

They are biologically oriented but psychotherapy is used extensively. Of the O.P.D. patients, about 10% are schizophrenic, and the same percentage prevails for

the inpatient population. The rest are mostly psychoneurotics, with a few central nervous system luetics, and manic-depressives. An interesting point is that they do not have a hard and fast distinction between the terms schizophrenic and schizoid.

There are few psychoanalysts in Japan. Most psychiatrists are connected with some hospital. Those connected with prisons, examine for the courts and usually study criminology. Child psychiatry is confined to the Umego-CKA hospital in Tokyo, where about 100 schizophrenic, as well as feeble-minded, children, are confined. They also have 500 adults in the institution.

Tokyo University also has a brain research institute with a wonderful specimen collection where comparative brain anatomy is studied in mammals.

The Matsuzawa Psychiatric Hospital (director, Dr. S. Hayashi) was established in 1874 as a municipal hospital on the outskirts of the city on 50 acres, and houses

¹ 1818 Newkirk Ave., Brooklyn 26, N. Y.

1,120 patients of whom 55% are male and 45% female. There are 30 buildings, of which 22 are used as wards, and the others, as kitchens, occupational therapy wards and auditorium. Of the population, 68-79% suffer from schizophrenia, 7-13%, general paresis, 3-5%, epilepsy, 1-5%, feeble-mindedness and 4-15%, others. There are a few neurological cases (Wilson's disease, Huntington's chorea, as well as manic-depressives and psychopaths). About 10% are criminal cases sent by the courts. In addition, they had 15 cases of drug addiction (morphine, heroin and benzedrine), as well as a few cases of alcoholism, head trauma, post encephalitic syndrome and cerebral arteriosclerosis. The hospital is affiliated with Tokyo University and has 18 doctors on the staff as well as 90 male and 110 female nurses. The physical plant, like the University, is dilapidated and in need of repairs. All patients sleep on the floor which is, of course, the custom in Japan. They use chlorpromazine, reserpine and other tranquilizers with fair results. ECT and insulin are used but not metrazol. They perform between 30 and 40 autopsies per year. An interesting point is that the suicide rate for young people in Japan is high, especially for females, but no definite reason can as yet be ascribed. Also, since the war, a lot of benzedrine addiction has occurred, the symptoms so closely resembling schizophrenia (auditory hallucinations, delusions, feelings of strangeness), that special studies are going on.

The writer next flew to Tel Aviv, Israel. The largest psychiatric hospital in Israel is at Acre (550 beds). I visited the Bat Yam Government Hospital on the outskirts of Tel Aviv, established December, 1944, which is the second largest psychiatric hospital. Dr. Yarmolowitz, originally from Po-

land, is in charge, and there are 10 doctors on the staff. The one story buildings are in good repair, clean and efficient, and were originally built for prisoners of war.

This hospital has 380 beds with a population of 402, 60% females and 40% males. In general, there is an open door policy and patients are on either short or long leave. The atmosphere is cordial and friendly. The outpatient clinics average 420 per month. Since they started chlorpromazine (Largactil), they claim a reduction of more than 50% in ECT. However, for depressive and confusional states, ECT is still given, usually combined with chlorpromazine. Metrazol is very rarely used. Insulin is still used in early schizophrenia and catatonic states, although not as much as in previous years. Chronic patients remain about 5-8 years, depending on the home conditions of the patient. There is an excellent occupational therapy department with woodwork, looms for rug making and tablecloths, and basket weaving, etc.

In Israel, mental defectives are under the supervision of the Social Service Department, not the Health Department (which takes in the Department of Mental Hygiene).

Another mental hospital, Ben Yacov Hospital, originally a military barracks, has more than 320 beds. In Jerusalem, the chronic hospital has a "working village" with facilities for rehabilitation. In Neve-On, 100 tubercular psychotic patients are housed near Tel Aviv.

Suicide is common in Israel; about 4-6 cases per month. Many drug addicts (mostly opium) are treated at Bat Yam. These come from Egypt and Asia. There are also cases of heroin and hashish addiction, treatment for which is mostly with chlorpromazine.

HISTORICAL NOTES

GOTTLIEB BURCKHARDT, THE FATHER OF TOPECTOMY

CHRISTIAN MUELLER, M.D.¹

There is less talk these days about the so-called psychosurgical methods. But it was by way of leucotomy and topectomy that the first attempts were made to regularise the emotional oscillations of psychotics and to reduce tension states with motor and verbal agitation. Since then, the era of tranquilizers has intervened and has given us a more practical and less dangerous instrument to treat the mentally ill. Psychosurgery in turn has become interested in other procedures (pallidectomy) and other regions of neuropsychiatry (Parkinsonism). The great neurologist Egas Moniz is regarded as the inventor of psychosurgery. Yet a few years back it was discovered that a Swiss psychiatrist, Gottlieb Burckhardt, had attempted to attack the brain with the feeble means of the period long before Moniz. Since then, the name of Burckhardt is quoted in all treatises, especially in the U.S.A. But who knows more about Burckhardt than his name and Swiss origin? We have tried to find some traces of his life and thus to reconstruct this short chapter of Swiss psychiatric history.

Gottlieb Burckhardt (Fig. 1), was born 1836 at Basle, was a scion of the famous old Basle family of Burckhardt. His father was a doctor before him. Gottlieb studied at Basle, Goettingen and Berlin, and then became a general practitioner in his home town. At that period already he seems to have been interested in scientific problems. For instance, when obliged to spend some time at Pau for health reasons, he wrote a study of the climatology of that city. He was also passionately interested in nervous diseases and electrotherapy just like that other great Swiss psychiatrist and psychotherapist of

the period, Paul Dubois. Thus in 1873, he accepted the position of physician at the psychiatric University clinic of Bern, Waldau. In the same year he issued his most voluminous publication *Physiological Diagnostics of Nervous Diseases*.

He worked at the Waldau under old Professor Schaerer and their scientific or administrative discussions must have been rather animated; both were very sociable and musicloving, but also rather excitable men. At this time Burckhardt started to review important psychiatric publications in the *Korrespondenzblatt für Schweizer Aerzte*; he expressed his opinion frankly and didn't mince words. He cooperated on the memorial volume for Albrecht von Haller and in 1879 wrote the annual report of the Waldau.

During his years at Berne, his main interest was the physiology of the brain. He looked for correlations between brain temperature and mental disease. He also studied brain circulation and brain movements. His ideas, especially concerning oxygen consumption of the brain, were taken up and usefully applied in 1907 by Hans Berger, the future inventor of the encephalogram. Burckhardt collaborated regularly on the *Allgemeine Zeitschrift für Psychiatrie* and was probably at that time its only Swiss correspondent. In 1881 a young intern worked under him, who was to revolutionize world psychiatry: Eugen Bleuler. In 1882 he became director of the clinic Préfargier. This clinic is beautifully located at the lake of Neuchâtel and has preserved its noble, classicist, external appearance. There he continued his research, participated in meetings of the Neuchâtel doctors and published several papers, especially in the medical review of French speaking Switzerland, on aphasia, on a case of brain tumor, and on hypnosis. He delivered a number of lectures and continued his activities as critical reviewer.

¹ Oberarzt and Privatdozent, Psychiatric University Clinic, Burghoelzli, Zurich. Translation by Erwin H. Ackerknecht, M.D., Director, Institute of Medical History, University, Zurich. The author is indebted to Drs. Morgenthaler, Bern, and Riggenbach, Préfargier, for documentation.

In 1889 at Berne, his pupil and assistant Ludwig August Müller published a thesis on the topographical relations between brain and brain case. In an appendix, the author mentions that his chief, Dr. Burckhardt, has had the opportunity to check his methods of localisation during surgical interventions in the living. Thus Burckhardt must have performed such operations around 1888. This was rather daring as neither he nor his collaborator had any special surgical experience, when they operated in a small room at Préfargier. He acted probably with a twofold intention. Above all he hoped to invoke improvement in schizophrenics who suffered from hallucinations and asocial attitudes. But perhaps he also hoped to satisfy his scientific curiosity and to see confirmed his theories concerning the physiology of the brain.

His conceptions of the genesis of psychotic phenomena and their elimination were extremely simple and an offshoot of his physiological theories. He tried "to extract from the brain mechanism the emotional and impulsive element in order to bring back the patient to calm." He writes :

If excitation and impulsive behavior are due to the fact that from the sensorial surfaces excitations *abnormal* in quality, quantity and intensity do arise, and do act on the motor surfaces, then an improvement could be obtained by creating an obstacle between the two surfaces. The extirpation of the motor or the sensory zone would expose us to the risk of grave functional disturbances and to technical difficulties. It would be more advantageous to practice the excision of a strip of cortex behind and on both sides of the motor zone creating thus a kind of ditch in the temporal lobe.

Thus topectomy was born. Its immediate goal was to put an end to verbal excitation, to a logorrhea, which for Burckhardt was the point of departure of delirious ideas. The minutes of the operations give us exact data on the surgical technique used. It was extremely simple. After a morphine injection, the patient underwent chloroform anesthesia. The skin was incised, the vessels tied, trepanation was performed at the place indicated with an instrument of a diameter of 2.8 cm. After opening the dura

and the pia mater, Burckhardt took off the cortex a piece weighing about 1.5 g. Then he sutured. The operation had lasted from 9:15 to 12 a.m.

He kept a minute-book where he recorded with his own hand his operations. Burckhardt sometimes performed several operations upon the same patient. He also took impressive photographs of his patients (Fig. 2). The place of operation is clearly visible. Fig. 3 shows the brain of a patient who had been operated and died later. It also clearly demonstrates the operatory lesion. It is amazing that operations performed with very simple instruments, in general did not produce dangerous hemorrhages. Fig. 4 shows the instrument used by Burckhardt, which is still kept at Préfargier and which we reproduce with the kind permission of the present director, Dr. Riggenschach.

In certain cases Burckhardt had to operate several times in order to come closer to his goal of interrupting transcortical connections. He was asked whether his results really justified an intervention which was not without dangers. He answered that in spite of the small number of cases and of favorable results, he felt the operation amply justified in view of the otherwise unavoidable psychological deterioration which awaited these patients. Burckhardt seems to have operated 6 or 7 persons. The exact number is not known.

All patients were what we would call today chronic schizophrenics. On account of their constant excitation, aggressiveness and uncleanness they had offered great custodial difficulties. Thus Burckhardt selected about the same type who was later submitted to leukotomy. We know that 4 patients became calmer after the operation, no longer needed isolation and were more accessible. Burckhardt himself did not speak of cures, but only of improvements. One patient died as an immediate consequence of the operation.

In 1890 he went to Berlin to a psychiatric meeting and communicated his results to a stupefied audience. The bomb had exploded. He published in the following year his "Ueber Rindenexcisionen als Beitrag zur operativen Therapie der Psychosen" in the *Allgemeine Zeitschrift für Psychiatrie*, but

his report had been quoted and commented upon before in several medical journals.

It is a strange fact that this sensational report concerning a daring therapeutic intervention was at the same time his last scientific accomplishment. A shadow fell upon his life and his activities. Bad luck and difficulties which we will not discuss here in detail pursued him.

Why did Burckhardt not continue his experiments? Why did he not operate other patients, though he had asked in his publications, that his colleagues control and continue his experiments? We do not have any direct answers to these questions. The fact that his immediate superiors felt uneasy with this bold operator might have been a factor. The death of one patient might have dampened his enthusiasm and made him more cautious. It is certain that the Swiss psychiatrists of the time were quite sceptical in regard to the value of his methods, judged them dangerous and therefore did not use them.

The death of his wife and of one of his

sons, professional troubles, all contributed to his leaving Préfargier and retiring to Basle. There he became again director of a clinic for nervous diseases, the "Sonnhalde." His death from pneumonia occurred in 1907, shortly after his retirement from this post. Except for two reviews of works of Moebius and Goldscheider and a necrology of his old chief, Professor Schaerer, Burckhardt did not publish anything after his paper on cortical excisions. Had he become afraid of his own daring which had driven him during his operations and which certain people had regarded as foolhardiness? We don't know.

One thing is certain: Burckhardt's name will always occupy a place of honour in the history of psychiatry, not so much because by accident he found something which with a more refined technique became a universally known method, but because he was a man who did not look at science as a form of recreation based on abstract theories, but as a necessary preparation for therapeutic action.

DR. WILLIAM CULLEN ON MANIA

ERIC T. CARLSON, M.D., AND R. BRUCE McFADDEN, A.B.^{1, 2}

One of the most important and influential figures in 18th-century medicine was Dr. William Cullen (1710-1790). Possessed of a thorough and varied medical education which included a medical degree from the University of Edinburgh, Cullen became Professor of Chemistry at the University of Glasgow in 1751. He later shifted to a similar position at Edinburgh, and there, at the age of 63, he was appointed Professor of the Practice of Medicine.

In this post he achieved wide fame as a dynamic and lucid teacher. The extent of his influence in medicine is generally acknowledged; less recognized is his relationship to psychiatric thought. His theories

in this field influenced such outstanding psychiatrists as Thomas Arnold and William Pargeter in England, Vincenzo Chiarugi in Italy, and Philippe Pinel, who translated one of his works for publication, in France. Nor was his influence confined to Europe; Benjamin Rush, "the father of American psychiatry," was among his students and he incorporated many of Cullen's concepts into his own medical and psychiatric thought.

An understanding of the core of Cullen's psychiatric thought can be attained by investigating and clarifying his concepts concerning one type of mental illness, mania. In his nosography Cullen divided his general category of neurosis, or nervous disease, into four orders: comata, adynamiae, spasmae, and vesaniae. Mania (and melancholia) fell into this last group, which Cullen defined as disorders of intellectual function, and therefore of judgment. The

¹ From the Department of Psychiatry of the New York Hospital (Payne Whitney Clinic), Cornell University Medical College, New York, N. Y.

² This investigation was supported in part by a Research Grant (M-2146) and a grant for undergraduate teaching, from the National Institute of Mental Health, U. S. Public Health Service.

distinguishing characteristics of mania were "violent anger, . . . furious violence, . . . impetuous will, . . . false judgment, . . . mistaken opinion, . . . raving, . . . unusual force in all voluntary emotions, . . . insensibility or resistance of the force of all impressions, and particularly a resistance of the power of sleep, of cold, and even hunger."

Basic to Cullen's psychiatric thought were his neurophysiological theories. In Cullen's system, the brain (which was not completely dependent on stimuli for its action) was an active organ producing a hypothetical nervous fluid which was the final product of certain constituents of the blood. Fundamentally, the amount of nervous fluid in the body determined the amount of nervous energy available, and the amount of nervous energy in turn ultimately determined the health and disease states of the body. Cullen thought that the amount of energy was dependent not only on nervous fluid, but also on the state of the brain fibers and on more general factors such as the age of the individual, his hereditary background, and the state of his physical and mental health. The condition of the nervous fluid (a newer term for a concept closely akin to Galen's "animal spirits") was obviously dependent on the state of the circulatory system; it was also dependent on the state of the organs, since, in Cullen's concept of "sympathy," the brain could affect, or be affected by, certain organs of the body (primarily the stomach, the genitals, and the uterus).

Cullen strove to discard the concepts of the ancients and to modernize medical theory. For this reason, although he acknowledged his debt to the chemical and mechanistic concepts of Herman Boerhaave (1668-1738), he condemned Boerhaave for his neglect of the nervous system. Cullen's approach to medical theory was largely physiological and mechanistic, but he too strayed from the path of pure mechanism when, in discussing the relationship between the brain and the mind, he was forced to bring in the immaterial intercession of God. He rebuked Friedrich Hoffmann (1660-1742) also, because, although Hoffmann had stressed the significance of the nervous system, he had not accorded it its rightful pre-eminence in his system, to

the exclusion of the ancient humoral theories. Cullen himself, however, retained some traces of ancient doctrine: he adopted some of Hoffmann's concept of spasmodic tension versus atony, which was only a modification of the ancient methodistic doctrine of *strictum et laxum* of Asclepiades.

Also relevant to understanding Cullen's physiology is an awareness of his acceptance of the Greek concept of *vis conservatrix et medicatrix naturae*. By this term he meant the tendency of the body to resist any untoward change, specifically, to resist any increase or decrease in the store of nervous energy. In this doctrine Cullen approached the concept of animism of Georg Ernst Stahl (1660-1734), but he rejected Stahl because his concepts were immaterial; Cullen felt that this phenomenon was a purely physical force, dependent on physical laws.

The causes of mania were various but primarily physiological. Cullen believed that an organic lesion of the brain could interfere with brain energy, and cited Morgagni's assertion that post mortem examinations revealed brain damage in maniacs. In cases where no lesions were found Cullen suggested that certain "morbid" changes might have taken place which passed unnoticed by the dissector. Irritations of the peripheral nervous system as well as such emotions as anger could increase the total nervous excitement and therefore lead to mania. Other factors affecting the course and outcome of mania were related to Cullen's concepts of temperament, which were ancient in origin. According to Cullen, the form of mania affecting persons of a "sanguine" temperament was much less serious and more amenable to treatment than the form striking persons of a "melancholic" temperament. Unfortunately, Cullen observed, mania occurred more frequently in persons of the latter disposition.

In all cases, however, the general measures taken to treat insanity were directed at (a) removing the physical and emotional causes of the nervous excitement, and (b) lessening the excitement already present. In accord with this scheme Cullen recommended that violent maniacal persons be subject to complete restraint and confinement. Both to calm the patient and to fa-

cilitate further therapy, Cullen suggested that a strait waistcoat be used as a restraining device, and that confinement take place in a dark, quiet room away from all familiar objects and acquaintances. This latter precaution was intended to preclude any strong emotional reaction to familiar objects, since such a reaction would serve only to increase the excitement and to complicate the course of the disease.

Since fullness of the blood vessels contributed to the general nervous excitement and since this excitement could produce insanity, evacuation of the body fluids was an important therapeutic instrument. Consequently, Cullen recommended blood-letting, purging, vomiting, and blistering. Shaving the head, applying cold to it, and throwing the patient suddenly into a cold bath were also thought helpful. Another method of restricting the amount of energy available to the system was to feed the patient a non-nourishing diet. Drugs, especially opium, could also be effective in limiting nervous energy by calming the excitement in the central nervous system. (Opium was considered a two-edged therapeutic sword, however, because it also acted as a stimulant to the circulation, increasing the amount of energy available to the central nervous system and consequently in-

creasing the excitement. So Cullen felt it was safe to use only when the excess excitement arose primarily in the nervous system.)

What seems to us now as some of Cullen's harshest treatment resulted from his theory that fear reduces the amount of nervous excitement. According to this thinking, awe and fear were essential in the treatment of insanity even if "stripes and blows" were necessary to produce this emotional state in the patient. Cullen did recognize that there was a thin line between instilling fear in a patient and simply punishing him without reason, and recommended that blows be used only when necessary and only under the discretion of someone who could be trusted.

Non-medical treatment played a small part in Cullen's approach to the maniac. He felt that hard and constant labor could be useful since it would divert the mind from its injurious train of thought. For this same reason he suggested extended journeys and other means of distracting the maniac's attention.

Thus, in building a theory on medical hypotheses, Cullen provided the rationale for the strong and vigorous treatment which to our contemporary minds seems primitive and brutal.

COMMENTS

DR. JOHN CONOLLY'S CROONIAN LECTURES 1849

Dr. C. R. Birnie, Physician Superintendent to St. Bernard's Hospital, Southall, has made a fine contribution to World Mental Health Year by having reprinted in book form the Croonian Lectures delivered by Dr. Conolly before the Royal College of Physicians, London, on some of the forms of insanity and their treatment.

These lectures were delivered in 1849; they appeared in the *Lancet* in October and November of that year and also in a small privately printed edition. The latter is now virtually unobtainable. Even as early as 1859, Dr. Lockhart Robertson complained in the *Journal of Mental Science* that these lectures in their separately published form "are hardly now to be had." Dr. Robertson added that they "contain in the most perfect English a long way the best description of the several forms of insanity in our language."

Dr. Conolly, who gained world wide fame for his humane treatment of mental patients, is perhaps best remembered for having abolished all forms of mechanical restraint. He was appointed Resident Physician to Hanwell Asylum June 1, 1839. "After 20th September of the same year," Dr. Birnie reports in his informative preface to the 1960 edition of the Croonian Lectures, "there was never an instrument of restraint used—John Conolly had swept them all away." It was true the humanitarian movement was already under way and non-restraint had been practised both in England and France, but Conolly "was the

first to abolish such restraint entirely and on such an extensive scale in a public asylum, and it was a cardinal principle with him that it should never, in any circumstances, be employed. His fervor and enthusiasm were such and his written and spoken word so powerful, that, during his twelve years at Hanwell, a revolution was effected in the treatment of the insane in Britain. Hanwell acquired an international reputation and visitors to the asylum came from far and wide."

Dr. Birnie gives an interesting sketch of the life of John Conolly. For four years he was professor of the practice of medicine at University College, London. Two other items are of special note. He had practised several years at Stratford-on-Avon and "was active in organizing successful opposition to the proposed removal thence of Shakespeare's remains." He was also associated with Sir Charles Hastings in founding the medical society which became the British Medical Association. Sir Charles has told the fascinating story of the birth and career of the B.M.A. and the B.M.J. in a recent volume.

Concerning the new reform presently under way in Britain, Superintendent Birnie aptly remarks that in one respect the removal of "environmental restraint" (locked ward-doors) is a logical extension of Conolly's own non-restraint system.

The present 85-page reprint of the Croonian Lectures contains an excellent portrait of John Conolly, M.D., D.C.L. (1794-1866).

CORRESPONDENCE

EGO

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : I must confess I was grieved to discover this evening in an accepted American textbook of psychiatry, in the space of one paragraph, four references to "the ego" as "it." I think it unfortunate that so human a trait as "the ego" should be saddled with so mechanistic a pronoun as "it." I would like to suggest three other—and I think, better—solutions.

In the first place we might say "the ego, he . . ." This imparts a certain human quality, possibly with a Teutonic flavor, suggesting masterfulness, power and also pride. It certainly seems more positive than "it."

Should that not strike our fancy, we might say, "the ego, she." Ships are so designated, and with affection. Based on current con-

cepts of the importance of early mother-child relationships, the feminine gender may, in fact, be more accurate, not to mention a certain nostalgia of affection and warmth.

A last resort would be to abandon the idea that "the ego" was either "he," "she," "it"—or even "they." That might lead to the realization that ego is not a "thing" but a manner of designating certain psychological processes. We might even get into the habit, instead of saying "the ego," of saying "ego functions" or "ego processes." Perhaps this is too much to hope for, and, if so, the "he" or "she" would seem preferable to the "it."

TWO EARLY REPORTS ON THE EFFECTS OF SENSORY DEPRIVATION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : The recent publication of 3 reviews (1, 2, 3) and 2 research studies (4, 5) will suffice to attest to the significance of the effects of the reduction of sensory stimulation upon physical and physiological, psychiatric and psychological variables: several additional experimental reports may be found in the April, 1960, issue of this *Journal*. Studies of psychiatric disturbances following cataract extraction (6) and hearing loss (7) also appear relevant to this problem. Neither the reviews nor any of the research studies which I have examined note the following reports published shortly after the turn of the century.

Clouston (8) in a chapter entitled "Rarer and Less Important Clinical Varieties of Mental Disturbance" summarizes his experience with individuals who became blind or deaf by noting that

It seems as if they were so cut off from social intercourse and the outer world by their deafness that their subjective experiences became objective realities to them. In the case of all men the senses correct many "delusions, and the impressions from the senses streaming in on the mental areas from the outer world are the best preservatives of mental health" (p. 666-667).

Although it is difficult to evaluate the relative effects of sensory deprivation *per se*, as opposed to the psychological effects of the loss of vision or hearing, the conclusion Clouston reaches is quite sophisticated.

An article by Bolton (9) is also surprising in this regard. Bolton reports on 10 cases of "dementia following sense deprivation" (6 male, 4 female) whose deprivation was either congenital or acquired and included hearing, vision or both. He discusses the difficulties in psychological development attendant upon sensory deficit and empha-

sizes the role of language and perceptual processes. Bolton summarizes as follows :

In persons who acquire sense-deprivation later in life, the mental stress involved on the one hand in the sense-disability, and on the other in the more or less unsuccessful attempts to revive the related memories which tend to pass more and more into the permanently sub-conscious, or to replace the absence of these memories by the integration of percepts and concepts on an unusual sensory-memorial basis, often, or perhaps invariably, results in the development of irritability, or depression, or general emotional instability.

In this case we see that the author is aware of the possible confounding effects of the loss of a sense modality over and above the secondary, sensory deprivation, effects.

NEWS AND NOTES

THE TITUS HARRIS SOCIETY.—The department of neurology and psychiatry of the medical centre of the University of Texas was established in 1926, with Dr. Harris, assistant professor of medicine, as head. In 1930 his department was certified by the American Board of Psychiatry and Neurology as a graduate training centre, and since that date he has supervised the training of 164 psychiatrists.

These men constitute the newly-founded Titus Harris Society, nearly 150 of whom gathered in Galveston for the first reunion and scientific meeting of the society, September 17, 1960. An all-day scientific session was followed by a dinner at the Galveston hotel honouring Dr. and Mrs. Harris.

Dr. Abe Hauser of Houston, Dr. Harris' first graduate and president of the society, stated that annual meetings are to be held in various Texas cities.

THE PARACELSUS MEDAL.—At the XIVth General Assembly of the World Medical Association and 63rd Deutsche Aerztetag convening in West Berlin Sept. 16, 1960 three doctors were awarded the Paracelsus Medal.

This award was established in 1952 as the highest honour bestowed by the Deutsche Aerztetag (German Physicians Day) in recognition of highly important contributions to medical science and service.

The physicians so honoured were: Dr. Curt Emmerich of Baden-Baden for the memorial he established to the reputation of the medical profession in his book *The Invisible Flag* wherein he demonstrated that doctors everywhere throughout the ages, under the obligation of the Hippocratic oath, have worked to protect life and reduce human suffering. This book has been published in 8 languages.

Dr. Walter Stoeckel of Berlin, Professor of obstetrics, gynecology and urology, for his great contributions to medical science, practice and literature. When during the war, which overtook him in his advancing years, he endured the trials resulting from the destruction of his clinic, he devoted him-

self faithfully to the principles of duty and labored for the safety and welfare of his patients.

Dr. Louis H. Bauer of New York City, Secretary General of the World Medical Association, in recognition of his services to the medical profession of the world, in upholding the freedom and honour of the profession in scientific, social, and economic relations; and particularly for his valuable work in the administration of the global organization of the doctors of the world and his friendship toward the German physicians.

REISS-DAVIS CLINIC FOR CHILD GUIDANCE (LOS ANGELES).—The Clinic will hold its seventh annual Institute of Child Psychiatry on November 12, 1960, at the Ambassador Hotel, Los Angeles, California. This meeting is offered to pediatricians and general practitioners in the Southern California area. Program this year will have Dr. Fritz Redl, President Elect of the American Orthopsychiatric Association, as guest speaker. Theme of the meeting will be "The Hyperactive Child."

For further information write to the Reiss-Davis Clinic for Child Guidance, Rocco L. Motto, M.D., Director, 715 North Fairfax Avenue, Los Angeles 46, California.

U. S. PUBLIC HEALTH COURSES IN EMERGENCY SERVICE.—Four national courses to train medical and health personnel for emergency services will be held during the current fiscal year by the U. S. Public Health Service and the Office of Civil and Defense Mobilization.

All courses cover basic civil defense concepts, current information on biological, chemical, and radiological warfare, and community disaster planning. Emergency services training includes the setup and operation of a Civil Defense Emergency Hospital, treatment of water to make it safe for use, decontamination of food and milk, mass casualty care, and medical self-help. Faculty will be comprised of governmental and

nongovernmental experts in the respective fields.

Tuition and housing and approximately one-half the necessary travel expenses can be provided without cost to students.

Further information on training courses and other Health Mobilization activities may be obtained from State Health Departments or Civil Defense Offices, or from Regional Offices of either the Department of Health, Education and Welfare or Office of Civil and Defense Mobilization.

ARMED FORCES FORENSIC SCIENCES SYMPOSIUM.—The second Forensic Sciences Symposium, to discuss problems of mutual interest to medical, legal and law enforcement officers in the Armed Forces, other governmental agencies and the civilian community, will be conducted at the Armed Forces Institute of Pathology, Washington, D. C., November 8-10, 1960. The symposium will be composed of lectures, panels, and demonstrations of the scientific methods used in criminal investigations.

Among the topics included are "Fingerprints and Footprints," "The Role of the Armed Forces in Criminal Investigations," "Forensic Pathology Cases," "Instrumental Deception Detection," "Psychiatry and the Law," "Rape and Sex Offenses," "Drug Addiction," "Toxicology," "Firearms Identification and Wound Ballistics," and "Court Testimony and Presentation of Evidence."

A limited number of spaces for civilians are available, and interested civilian physicians, lawyers and law enforcement personnel should submit requests for attendance to: The Director, Armed Forces Institute of Pathology, Washington 25, D. C.

UNIVERSITY OF CALIFORNIA SYMPOSIUM, "CONTROL OF THE MIND."—Some of the most distinguished international scientists and scholars will take part in a 3-day symposium on "Control of the Mind" January 28-30, 1961 at the University of California Medical Center in San Francisco.

Presented by the U. C. Medical Center and University Extension through the financial assistance of the Schering Foundation, the program will feature a broad interdisciplinary approach, surveying "the fac-

tors in the control of the mind and how they interact with each other."

Topics included: psychopharmacology, psychologic, sociologic, and historical factors, religion, mass communication, political philosophy, and other related subjects.

Further information and application for enrollment may be obtained from the Department of Continuing Education in Medicine, University of California Medical Center, San Francisco 22, California.

A NATIONAL CENTER FOR HEALTH STATISTICS.—This center has been established in the U. S. Public Health Service to bring together the major PHS activities concerned with measurement of the health status of the Nation and identification of significant associations between characteristics of the population and health-related problems.

Initially it has two Divisions: the U. S. National Health Survey, and the National Office of Vital Statistics. It will supplement but not supplant the statistical work associated with particular Public Health Service programs, and which will continue as integral parts of those programs.

Dr. Forrest E. Linder, who has been Director of the National Health Survey since its inception in 1956, is Acting Director of the new unit.

The Center will have a staff unit for statistical programming, for data processing expertise, to encourage maximum use of improved techniques in health statistics collection and analysis, and to make technical assistance available to other workers in this field.

Another staff unit, for health trends analysis, will analyse and interpret health and vital statistics from a variety of sources.

WINTER SEMINAR IN GENERAL SEMANTICS.—The 23rd winter intensive seminar will be held in the Barbizon-Plaza Hotel in New York City, Dec. 27, 1960-Jan. 1st, 1961. O. R. Bontrager, Ph.D., a former student of Count Korzybski, will conduct the seminar.

Enrollment limited to 25. Tuition \$100.00.

Information may be obtained from the Institute of General Semantics, Lakeville, Connecticut.

UNIVERSITY OF PITTSBURGH REHABILITATION TRAINING.—A new Rehabilitation Counselor Training Program at the University of Pittsburgh has been authorized by the U. S. Office of Vocational Rehabilitation. Candidates accepted in January, April, and September of any year. Stipends range from \$1,800 to \$3,400; for information write to Dr. L. Leon Reid, Dept. of Special Education and Rehabilitation, University of Pittsburgh, Pittsburgh 13, Pa.

SALMON LECTURES.—The annual Thomas William Salmon Lectures, the preeminent American psychiatric lectureship, will be delivered on Monday, December 5, at the New York Academy of Medicine, 2 East 103rd Street, New York, at 4:30 P.M. and 8:30 P.M.

The 1960 lecturer will be Harry F. Harlow, Ph.D., Research Professor at the Uni-

versity of Wisconsin since 1930. During the war Dr. Harlow was on leave from the University of Wisconsin to serve as Chief Psychologist for the U. S. Army.

Much of Dr. Harlow's work in the past 30 years has dealt with the behavior of rhesus monkeys. He has analyzed the nature and development of their learning and in the Salmon Lectures he will discuss first "The Affection of the Infant for the Mother," and in the evening he will discuss "Affection Between Infants and Adolescents."

The Salmon Lectureship, established in 1932, is under the aegis of the Salmon Committee on Psychiatry and Mental Hygiene. The committee is appointed by the Council of the New York Academy of Medicine. The lectures, for the advancement of psychiatry and mental hygiene, are designed as permanent contributions to the field of medicine and will be published later in book form.

BOOK REVIEWS

ADOLESCENT AGGRESSION. A STUDY OF THE INFLUENCE OF CHILD-TRAINING PRACTICES AND FAMILY INTERRELATIONSHIPS. By **Albert Bandura and Richard H. Walters.** (New York: Ronald Press, 1959, pp. 473. \$7.50.)

This is a study by two psychologists of the origins of aggression in adolescents. The data were obtained from interviews with 52 adolescent boys and their parents. Twenty-six were "aggressive boys." Most of them were secured through the county probation service; the others from the guidance department of the school. Some of them were in custody at the time of the study, the rest were on probation. A few had been in correctional institutions. Their ages ranged from 14 to 17.

A control group of 26 was selected as being "neither markedly aggressive nor markedly withdrawn." They were matched with the aggressive boys with respect to age, intelligence, father's occupation and area of residence. In addition to the interviews each boy was given a "thematic deviation test" composed of 10 pictures indicating aggressive situations and a "story completion test" composed of 8 stories.

The bulk of the book consists of abstracts of material obtained and of statistical evaluations. A main finding relates to the importance of the "dependency conflict" and "dependency anxiety" as it relates to aggression. An overall view of the characteristics of aggressive boys is presented, stressing such attributes as open antagonism to authority, a feeling of being rejected by parents, affection for their mothers coupled with resentment against their fathers and confusion of sex and aggression.

The book contains a number of instructive comments. It lays great emphasis on any disruption of the father-son relationship. The authors explain the neglect of this in the literature by the fact that the mother is usually "the more accessible parent." They offer valid criticism of the too schematic distinction between psychopathic and neurotic delinquents. They point out that the phenomenon of recidivism, for example, is assumed to indicate in neurotic children severe feelings of guilt; in those called psychopathic, on the other hand, the same phenomenon is apt to be regarded as evidence of an inability to form just such feelings of guilt.

As a whole, this book is of great importance

because it so well illustrates a trend in behavior research which is currently fashionable and subsidized by foundations. Despite its appearance to the contrary, this trend is essentially unscientific, furnishes results that are invalid, and is socially evasive. Since in this respect this book is typical, a few of its shortcomings should be at least briefly mentioned.

The authors speak of "interviews of a semi-structured type." This is nothing but the much used and abused questionnaire method which is so different from—in fact practically the opposite of—a clinical psychiatric examination. The ratings were done by undergraduate psychology students. They were based on rating scales which again give the impression of scientific accuracy but which are subjective and unlikelike abstractions. For example, this scale is used as a "measure" of the extent to which parents encourage their sons to seek help from them: 1) not at all permissive; 2) slightly permissive; 3) parents expect boy to work out things for himself; 4) generally permissive; 5) entirely permissive. Such primitive categorical classifications inevitably vitiate statistics based on them.

The entire approach is essentially unclinical. Explanations and interpretations are not enough unless there is a clinical organization of the material. *Aggression* is a term used generally and in this book with considerable ambiguity. In the development of Freud's thought it played a great role, being regarded originally as sadism, a part of sexuality. Later it was used by Freud interchangeably with destruction. Now it often serves as a cover word for different phenomena. The authors say that they specifically avoid the term *delinquency*. Their material, however, consists of delinquents. By the term "anti-social aggression" the authors mean "injury to persons or property." They make frequent reference to anger, hostility, combativeness, "undersocialized aggressiveness," "violent aggression," etc. All of these attributes may be manifestations of very different psychological processes.

The word *guilt* is used as if it meant *feeling of guilt*. One is an objective fact, the other subjective. Both are important, but they are not the same thing.

A monotype standard of personalities is assumed. The idea of comparing a control group in such an intricate field is dubious. The differences in family situations, in social and

economic status, *etc.* may be so decisive that no statistical refinement can overcome the errors contained in the data.

There is an inherent assumption that all data excluded are irrelevant. What appear as concrete statistical results are really statements based on an arbitrary reduction of factors and arbitrary sampling. Clinical judgment should come first, and statistics afterwards, not the other way around.

The authors make the basic assumption that by their method the possible influence of "sociological factors was reduced or eliminated from the start." Thus they exclude the sociological dimension which is so important for any understanding of either adolescence or aggression (however defined).

The shortcomings of this book form a typical pattern. Some day a foundation should finance research to find out why foundations finance this type of research.

FREDRIC WERTHAM, M.D.,
New York, N. Y.

PSYCHIATRISCHE UND NERVENKLINIK. By Kurt Kolle. (Stuttgart: Georg Thieme Verlag, pp. 252, 1959.)

Following the example of Kraepelin whose second successor in the chair of psychiatry at the University of Munich the author is, Kolle describes the case histories of 187 psychiatric and neurological patients as they were presented and discussed in his clinical lectures to undergraduate students. As he states in the preface, his main intention in writing his book was a didactic one. However, the commentaries which accompany the individual case presentations have a high scientific standard. The nosological system followed in these lectures is that of Kraepelin. Phenomenological psychopathology as represented by Jaspers and his teachings is closely interwoven. Another aim of Kolle's book is to promote neuropsychiatry and its central position in medicine. The individual cases covering the whole field of psychiatry are described in a vivid and lucid fashion. Each lecture is introduced by a short quotation from Goethe's writings whose great admirer and diligent student the author has been all his life.

WHY MARRIAGES GO WRONG. By James H. S. Bossard and Eleanor Stoker Boll. (New York: The Ronald Press Company, 1958, pp. 224. \$3.50.)

In an easily readable volume the authors discuss certain of the social factors which con-

tribute to unsuccessful marriages. They describe in an astute and entertaining manner how the individuals of diverse cultural, economic, and religious backgrounds may marry due to the American emphasis on romance and individualism. They emphasize that our high divorce rate is a result of a conflict due to these rapidly changing cultural elements.

The content of an otherwise thoughtful book is marred by a dismissal of psychiatric thought on the subject. They claim that the psychiatrist takes into consideration only the individuals in marriage without regard to sociological variables. A review of current psychiatric literature would indicate that their criticism is an unjust one.

For the reader who already has knowledge of personality factors affecting marriage relationships this book will increase his understanding of some of the current broader social factors which also lead to marriage failure.

WILLIAM H. WAINWRIGHT, M.D.,
Cornell University Medical College,
The New York Hospital, N. Y.

PHARMACOLOGY IN MEDICINE. Edited by V. A. Drill. (New York: McGraw-Hill Book Co., Inc., Blakiston Division, 1958, pp. 1243. \$19.50.)

This textbook of pharmacology is one of the best I have read. It is impossible to review in detail the excellent discussion of pharmacological theory and practise for a journal of psychiatry. I have therefore given particular attention to the sections which are more interesting to the eclectic psychiatrist. Dr. Drill has chosen a most competent group (86) of scientists including 24 who are not professors of pharmacology, to cover the subject. It is divided into 19 sections containing 88 chapters.

There are a couple of statements with which one could quarrel. McIntyre in chapter 12 states "the use of curare in ECT has been considerably reduced." To the contrary, many psychiatric units routinely use modified ECT to the degree that there was recently a lawsuit in England by a patient who had received unmodified ECT against his psychiatrist for having not used some curare-like substance. Secondly, in chapter 16 entitled "The Alcohols," it is said "the chronic alcoholic . . . is distressed and upset without the euphoria produced by alcohol in his system." I do not find euphoria in the alcoholics I have treated. They continue to drink very often because of the great distress they experience when sober.

In chapter 25, W. C. Wescol in reviewing the autonomic nervous system reports that epinephrine is oxidized to a quinone adrenoxine. Adrenoxine was postulated as an oxidation product of epinephrine but has never been crystallized. On the other hand, adrenochrome is a well known quinone derived from epinephrine and can now be easily synthesized as stable crystals. Drill (chapter 65), in his discussion of lipid metabolism does not refer to nicotinic acid which provides the most practical way of lowering cholesterol levels in humans according to numerous authors publishing since early 1955.

These are, however, minor criticisms and are more than compensated for by the great value of this work. I was particularly impressed by chapter 24 "Drugs Affecting Behavior" by P. B. Dews, not only because such an account appears in a textbook of pharmacology but because of its excellence. The material is treated in a logical way by starting with a discussion of the parasympathetic system and its mediator acetylcholine, then the sympathetic nervous system and 3 amines, norepinephrine, epinephrine and isopropyl norepinephrine. Finally there is a discussion of serotonin which can modify brain function but has no proven physiological relationship. The assumption behind this chapter is that a knowledge of these chemical moderators will be helpful in the consideration of psychotomimetic drugs like LSD and mescaline. Finally drugs used by psychiatry are divided into psychomotor stimulants such as cocaine, amphetamine, pipradol, *etc.*, tranquilizers such as chlorpromazine, and the Rauwolfia drugs and milder compounds such as meprobamate and azacylanol. These compounds have developed so quickly many of the new ones used today are not listed.

Chapter 19 on "Drug Addiction" by M. H. Seevers is particularly well done. Dr. Seevers is disturbed by the irrational way in which society deals with the problem. "It has surrounded the addict with an aura of mystery and assigned him to the criminal class. A medical problem has been turned over to the criminologist. The very laws designed to prevent the situation assure its perpetuation by creating bootleggers and peddlers. The individual is not an addict because he is a criminal—he is a criminal because he is an addict." Alcohol, by far the most addicting drug of all, qualitatively and quantitatively by any acceptable definition of the term is accepted by society. According to Seevers (and this opinion is shared by many authors who have studied the problem) mescaline, the most

active alkaloid psychologically in Peyote, is not an addicting drug. No peyotist has ever applied or been admitted to the U. S. Public Health Service Hospital at Lexington. (Peyote can be used in Canada only by medical prescription.)

This book should be easily available to psychiatrists, for no matter what their orientation, they are using drugs more and more and they will be better therapists when they know something of the biochemistry and pharmacology of their compounds.

Director, Psychiatric Research,
University Hospital,
Saskatoon, Canada

THE FAMILY IN CONTEMPORARY SOCIETY. The Eastern States Health Education Conference. Edited by *Iago Galdston, M.D.* (New York: International Universities Press, Inc., 1958, pp. 147. \$3.00.)

The 9 papers in this volume were presented in 1957 in a conference on the family sponsored by the New York Academy of Medicine. The purpose: to bring together workers on "practical" problems of the family-oriented health education and investigators of "theoretical" problems of the family. However, the published volume gives little hint of how such studies may be of value to health educators. The two papers dealing directly with health education practices appear, in relation to the rest of the volume, to be floating unmoored in a foreign sea.

Most of the papers, however, are of considerable interest for psychiatrists and behavioral scientists. Marvin Opler presents an admirable, concise but information packed, review of anthropological studies of cultural variation in the form of families. This paper joins well with a discussion by John Spiegel of his comparative study of Irish-Catholic and Protestant old American families in the Boston area. Spiegel notes that subcultural variations in family patterns make it impossible to describe a *standard* pattern of family life in the United States. He develops the view that the homeostatic mechanisms of stability within the family, and their relative breakdown in "sick" families, must be defined in terms of the particular subcultural pattern of the family.

Nathan Ackerman describes vividly a picture of the white middle-class urban American family and its especial emotional vulnerabilities. He regards the contemporary, "peculiar disharmony of the individual's relations with urban society" as tending to throw each in-

dividual back upon his family group for reassurance as to his loveliness and worth, into a compensatory and often maladaptive family "togetherness." Other papers of psychiatric interest include a preliminary report by William Westley of a study of the families of emotionally healthy adolescents and a review by Paul Glick of the great variety of changing socioeconomic characteristics of American families.

National Institute of Mental Health,
Bethesda 14, Md.

DAS ZENTRAL-NERVENSYSTEM ALS SYMBOL DES ERLEBENS. (The Central Nervous System as a Symbol of the Modes of Experiencing.)
By F. S. Rothschild. (Basel, New York : S. Karger, 1958, pp. 142. sfr. 27.)

Communication through symbolization is an elementary capacity of life and not of man alone. To the degree to which a living organism expresses itself through symbolism and, through this symbolic communication, is able to become aware of itself in time and space, it not only lives (biologically) but also experiences (psychologically). The German "Leben" refers to the vital or bodily aspects of life, whereas "Erleben" expresses the psychic-spiritual (seelisch-geistig) aspects. "Erleben" roughly describes what we ordinarily call psychic; it results through the translation of the "vital layer" via symbolizations.

In paraphrasing the author, his central thesis is this: The role of the central nervous system is to make "Erleben" from merely "Leben" possible and it does so by way of symbol production and by being symbolic in its very structure. On this structure, both micro- and macroscopic, depends what kind of "Erleben" the organism will be capable of. Animal life has in the course of evolution developed symbolic structures, through the aid of which it can become aware of itself and is able to relate to itself. "Leben" understands itself through "Erleben." This "Erleben" is structure-bound; it depends upon a specific organization or configuration of the excitations in the CNS. These excitations can be understood and interpreted by the living organism because of their symbolic nature. The structure of these excitations in the CNS (with their dimensions in time and space) constitute the symbolic medium through which the structures of reality (with their dimensions in time and space) are interpreted.

The author reviews and discusses current concepts and solutions to the body-mind prob-

lem and the hypotheses in regard to the function of the brain. He feels that earlier animistic and mechanistic approaches can be overcome by looking at the brain structure and function as a symbol-system. His theory provides a new way of looking at the body-mind problem, avoiding both the artificial dichotomies and the logical pitfalls inherent in the monistic views. He marshals his facts in a clear, scholarly fashion. He is a phenomenologist *par excellence* and the breadth of his knowledge is neuroanatomy, neurophysiology and comparative biology is impressive; his interpretations of the symbolic aspects of structure and function of the CNS ingenious. Unfortunately none of these can be discussed in brief and it is hardly possible to exemplify here the author's methodology.

This book is not for the clinician, it is for the theoretician among psychiatrists, neurologists, neurophysiologists. It is particularly refreshing to have a primarily biocentric approach to the body-mind problem instead of the age old tortuous logocentric approaches. Whether the author has really accomplished the development of a unified theory of body and mind with the avoidance of all logical pitfalls is for future research to tell. In any case his is an important contribution to the basic sciences of psychiatry and neurology and the book deserves an English translation.

PAUL H. ORNSTEIN, M.D.,
College of Medicine,
University of Cincinnati.

THE PSYCHODYNAMICS OF FAMILY LIFE; DIAGNOSIS AND TREATMENT OF FAMILY RELATIONSHIPS. By Nathan W. Ackerman, M.D.
(New York: Basic Books Inc., 1958, pp. 379. \$6.75.)

This book is by one of the pioneers of the integrated family approach to mental disorder. The first and the last sections entitled, "Theoretical Aspects" and "Wider Perspectives" respectively appear to this reader the most important parts of the book because the author permits himself here to present more clearly his own views on the treatment possibilities and research methods in this complicated field.

The main parts of the book, devoted to the clinical aspects of family diagnosis and treatment, are more uneven and difficult to follow because of the changing focus and levels of abstraction. Thus the reader is led from a chapter concerned with the assessment of the disturbed child within the family setting to a discussion of disturbances in parental care and then back to problems of adolescents

which in turn is followed by a small chapter on psychosomatic illness and family disturbance. While all these chapters are worth while in themselves and illustrate the author's wide range of clinical experience and interest, they do not hang together too well for the reader, and it is difficult to remain oriented with regard to the different techniques or clinical settings in which the material was obtained.

There is a core of 50 families which have been studied by the author and his collaborators, but it is not clear to what extent individual chapters are concerned with the entire sample, or parts of it or, possibly, patients outside this group. Much of this material had been previously published and the effort to weld these different presentations into a continuum is not entirely successful. All the same, the book is a most important and welcome publication for everybody concerned with family treatment and research.

STEPHEN FLECK, M.D.
New Haven, Conn.

CONCEPTUAL AND METHODOLOGICAL PROBLEMS IN PSYCHOANALYSIS. Edited by *Leopold Bellak, M.D.* (Monograph from Annals of the New York Academy of Sciences, Vol. 76, Art. 4, pp. 971-1134. \$2.75.)

Dr. Bellak has compiled 5 papers and discussion held under the auspices of the New York Academy of Sciences in 1959. The first 3 are concerned with the Libido theory. Thomas Szasz takes issue with what he thinks are some of the implications to be derived from Freud's "Three Contributions to the Theory of Sex." Among these implications, according to Szasz, are that it (a) opens the way to the creation of a diversity of different instincts and drives, (b) makes human sexual behavior dependent upon anatomical and physiological factors in such a way as to leave little room for the understanding of the psychic contribution to that behavior, (c) suffers from an implicit moral view as to what constitutes normality, and (d) that Freud did not understand the role of object-relationship of the ego.

Dr. Alfred Stanton's "Propositions Concerning Object Choices" is the second contribution in which he summarizes 9 statements about object choices and discusses some of the difficulties we have with refinement of terms. These terms, it seems, cannot be refined as far as we would wish without further productive research. But this does not mean they cannot serve us. It need no longer be assumed that a concept to be useful must be "defined"

in terms of the operations used to measure it, and it certainly need not be observable; it needs only to be related by some kind of theoretical construction to something that is observable. The concluding paper in this group is Pumpian-Mindlin's: *Propositions Concerning Energetic-Economic Aspects of Libido Theory: Conceptual Models of Psychic Energy and Structure in Psychoanalysis.*

The two papers: "The Unconscious" by Bellak, and "The Structural Model" by Ostov conclude this monograph.

The constantly recurring theme and problems raised in these papers and more particularly in the discussions are the mutual interaction of empirical data on theory, and theory or conceptual models on observation. To keep these constantly in mind is no simple task for presenter, reviewer or reader. "What one may discover through a microscope and what is the nature of the microscope are two different areas of investigation" Ekstein is quick to point out in his lucid discussions of two of the papers.

The monograph cannot be viewed in a way which can indicate adequately the rich content of the papers and their discussion. I would not even say they can be "read" with ease but those who will "study" them cannot help emerging from the effort the better for their labor.

EDWARD C. ADAMS, M.D.,
Berkeley, Calif.

THE SAGE OF SEX. A LIFE OF HAVELock ELLIS.
By *Arthur Calder-Marshall.* (New York: G. P. Putnam's Sons, pp. 292, illus., 1959. \$5.00.)

The publication of this book in 1959 marked the centenary of the birth of Havelock Ellis. The author had spent some two years "in exploring and reliving this long and puzzling life." Ellis had died at 80.

Of the several biographies of Ellis in existence this is the fullest and most satisfactory as a straightforward account from birth to death, with some data as to family background and considerable material relating to the various persons, male and female, who had filled significant places in Ellis's life.

He had been given the name of Henry Havelock, the hero of the Indian Mutiny, who was a relative on his mother's side; but dropped the Henry and was henceforth known as Havelock Ellis.

Calder-Marshall was greatly assisted in writing this book by Mme. Françoise Delisle who, in 1917, a young French woman estranged

from her husband and wrought upon by the evil circumstances of World War I and by difficulties of livelihood too, had come to Havelock Ellis for help. She knew he had helped others in distress and he had invited her to come. That meeting seemed to them both like the intervention of a kind providence. Françoise fell in love with the patriarch with the spreading snowy beard and the flowing mane and he with her. Two decades and more they spent together. They were the happiest years in both their lives. This period is well documented in Mme. Delisle's memorial volume *Friendship's Odyssey*, from which as well as from Ellis' autobiography *My Life* and from many conferences with Mme. Delisle the author of the present work draws freely. (The name Delisle will be recognized as an anagram for D'Ellis.)

Havelock Ellis' literary range was vast, 37 of his books on many subjects, were published during his lifetime, and several, including *My Life*, posthumously. *The Dance of Life* (1923) he particularly valued as best setting forth his "philosophical outlook on life." This book had a surprising and unique experience; it became a best seller and went through many editions. His fame rests largely however on his *Studies in the Psychology of Sex* (7 volumes). The first volume in this series (on Inversion) was brought out in England and resulted in a lawsuit with Ellis and the publisher as defendants for producing a "filthy" book. The series was published in Germany and later in the United States.

In his discussions with Mme. Delisle, Calder-Marshall records that there was one point of disagreement—*re* religion. He declares that he, the author, is a Christian and Françoise seemed to think he was trying to read Christianity into Havelock's teaching. "One thing I will not tolerate" she said, "is that you should try to pretend that Havelock was a Christian." In *My Life* Ellis records that in his 'teens he went through a religious phase not uncommon in adolescence. But he was an omnivorous reader and "it was in the course of my reading that I slid almost imperceptibly off the foundation of Christian belief." Françoise, who was with him to the end, knew that he didn't get back on.

The marriage arrangements of Havelock Ellis and Edith Lees were perhaps unique in the records of this function. Though married, they were to maintain their separate existences, privacy and financial responsibility. Edith paid one-half of the cost of the wedding ring. They were to live in separate abodes, visiting each other only occasionally. They were married in the Registry Office. "Then," Havelock records,

"we each returned to our bachelor homes."

Ellis' absorbing interest in sex problems dated from adolescence when he became concerned about the question of his own virility. In marriage he condoned his wife's various Lesbian attachments knowing that as a sex partner he was not a very satisfactory husband.

In addition to inversion Mrs. Ellis was of a cyclothymic constitution. She was forever busy, often to the point of exhaustion. She gave lectures at home and in the United States and was overjoyed by the attention she received. There were also periods of deep dejection, sometimes with abrupt transitions, and there were two or three suicidal attempts. Toward the end of her life her agitation became more severe and the need of hospital treatment had to be considered. Fearing that her husband might have her committed as a mental patient she insisted on a legal separation. Such an instrument was actually drawn up and husband and wife signed it before witnesses. Then they went out and had lunch together. It was not intended that the legal action would make the slightest difference in their manner of living; but it gave assurance to the wife that her husband now had no power to place her in an institution.

Mrs. Ellis died in 1916 and was cremated. Havelock and two friends witnessed the consummation. "As I gazed at that beautiful sight, at that vast and seemingly liquid mass of golden intense heat . . . my pain . . . was merged into joy at the glory of the vision . . . that one whose spirit in life . . . had been a flame, should pass from the world in actual flame, a chariot of fire, to rise with the air, and to become one with the panorama of sky and sea. . . ."

At this time Havelock Ellis considered that he was an old man. The study and writings to which he had dedicated his life had been done. He felt that death might be near. In a sense the old life was finished. But unexpectedly, the following year, a new life began, for the first time a complete life, with that remarkable person Françoise Delisle—a *Wahlverwandschaft*, if ever such there was—and it lasted twenty-three years.

He had attained to a state of mind that one commentator spoke of as a "cathedral calm," despite the inner tensions that through so many years had painfully beset him.

At the close of his book Calder-Marshall wrote: "Havelock Ellis anticipated no survival after his death except in the hearts of those who loved him. This was not because he disliked the idea of life after death, but because he found it scientifically inconceivable."

The author gracefully dedicated his book to Françoise Delisle, the woman who helped him make it.

PSYCHOHYGIENISCHE VORLESUNGEN. EINE EINFUEHRUNG IN THEORIE UND PRAXIS DES SEELISCHEN GESUNDHEITSSCHUTZES. (Lectures on Mental Hygiene. An Introduction into Theory and Practice of the Preservation of Mental Health.) Edited by *Heinrich Meng*. (Basel and Stuttgart: Benno Schwabe & Co., 447 pp., 1958.)

✱ This is a collection of 40 lectures discussing ever so many facets of mental hygiene. The editor, Heinrich Meng, is emeritus professor of mental hygiene at the University Basel (Switzerland). Ordinarily, editors compose the introduction and the finale of such books. In this instance Dr. Meng did not only this, but contributed 14 lectures of his own, reaching from historical remarks via the mental hygiene of the pubescent and grown-up to that of the bodily damaged patient. Kallmann—New York wrote on Genetics, Eugenics and Mental Hygiene; Stengel—Sheffield on attempt at suicide and its relationships to suicide. Mental hygiene in Public Health is presented by Brockington—Manchester. Riggensbach—Préfargier reports about mental hygiene in the Swiss army. A theologian, professor van Oyen—Basel, took over the fortieth lecture on religion and mental hygiene. With the jurist (meantime deceased) Reiwald—Genf, the editor, in addition to all his already mentioned pieces, discussed the prophylaxis of crime. Dr. Meng was the leading mental hygienist in Switzerland during his active years with the university. This volume is, in fact, a monument to him, his ideals and achievements.

PSYCHOLOGY AS APPLIED TO NURSING. By *Andrew McGhie*. (Edinburgh and London: E. and S. Livingstone Ltd., 1959, pp. 238. \$4.50.)

This book is addressed primarily to student nurses, although the author hopes it will be useful to all nurses.

It is written in 4 parts; The Development of Personality, Human Motivation, Interaction with the Environment and Social Groups. Part

I is the longest and most detailed section of the book. Personality development is discussed through childhood, adolescence, adulthood and old age. In the chapter on childhood the normal psychological characteristics are first described, and at greatest length, as the basis for understanding human behavior; this is followed by a discussion of certain psychological disorders of childhood, and finally a consideration of the child in hospital. The same approach is used for the other chronological periods. Chapter II, Adolescence, is particularly valuable, both because it has, we believe, had less attention in the teaching of nurses than childhood and old age are now receiving, and because the student nurse is herself a late adolescent.

Part III, which is a discussion of learning and thinking, is valuable not only for its content but because this aspect of psychology also has received comparatively little attention in psychology courses in the nursing curriculum, which have tended to be centered almost entirely on the emotions.

The author questions certain current assumptions for which he feels there is very incomplete evidence, and gives his reasons. For instance, on the question of keeping the baby in the nursery except at the time of feeding, he says that since the child cannot form a permanent relationship with the mother in the first 6 months, separation in a nursery is unlikely to have "any effect on the newborn infant who probably is content to leave the anxiety to the psychologist." Rigid insistence on breast-feeding in all cases is also questioned.

It may surprise many nurses to read that their uniform is seen by the author as one of the causes of fear in the child entering the hospital for the first time.

The style is simple and clear, but the material is not over-simplified. The summaries and the questions at the end of each chapter are valuable. In conclusion the author states his hope that his readers will not "passively accept every statement without further thought." This is a warning which is needed by nurses.

This book is a very useful over-all view of the subject, which will not only be helpful immediately to the nurse but which should also lead to further study.

Univ. of Toronto

IN MEMORIAM

PETER JACOB FROSTIG, M.D.

1896-1959

Dr. Peter Frostig died of coronary occlusion in Los Angeles on October 21, 1959, at the age of 63. He occupied a prominent position in psychiatry in California; his contributions are known to many psychiatrists throughout the world.

Dr. Frostig was born in Belz, Poland, on March 25, 1896. He received his medical degree at the University of Vienna in 1921. Art criticism, psychology and philosophy were among his early interests. His postgraduate training in psychiatry and neurology was obtained under the guidance of Wagner Jauregg and in close association with Schilder, Gerstman and Economo. His classmate Otto Fenichel gave him a brief didactic analysis. Afterward Dr. Frostig himself practiced psycho-analysis for some years, during which he enjoyed the personal friendship of Alfred Adler.

From 1924 to 1932 he practiced psychiatry in Lwow, Poland, and began his research career there. He was superintendent and medical director of the Psychiatric Institute, "Zofioka," Warsaw, Poland, from 1932 to 1938. During his administration the Institute affiliated with the Medical School, and the government commissioned him to write a Polish textbook of psychiatry under rather unusual conditions. For four months of each of four successive years he visited and worked at psychiatric centers in Europe, gathering material for the book, which appeared in two volumes in 1932. In this way he came in contact with Kraepelin and Bumke in Munich; Bonhoeffer, Birnbaum, C. and O. Vogt in Berlin; M. Minkowski and Eugene Bleuler in Zurich. In Marburg he worked under Kretschmer, and was close to Eugene Minkowski in Paris.

While in Poland, Dr. Frostig published a number of papers in Polish and a monograph in German on "Das Schizophrenie Denken," based on studies in the phenomenological school of Husserl. He had a stand-

ing invitation to present clinical seminars (in which he excelled) at the University of Vienna, where he also published research studies. In 1936 Prof. Otto Poetzl, successor to Wagner Jauregg, suggested that Dr. Frostig start an experimental series to parallel that of Sakel on the effect of large doses of insulin in schizophrenia. He standardized insulin shock therapy on 1,000 cases of schizophrenia. The report was published in Polish, German and French and translated by Dr. Joseph Wortis for the *American Journal of Psychiatry* and *Archives of Neurology and Psychiatry*. This standardization has been widely accepted.

In June, 1938 he was invited to this country to present his data and the techniques of insulin shock treatment at the Harlem Valley State Hospital, where he met Dr. Harold Himwich. Dr. Frostig had made a beautiful analysis of the behavioral changes of insulin hypoglycemia and noted that the symptoms did not come in a haphazard way but were associated in a series of syndromes. Then he and Dr. Himwich found that the syndromes had relation to the decrease in CMR, some coming with a relatively small fall and others only with a profound decrease in CMR. To test this hypothesis they gave smaller or larger amounts of glucose so that they could arouse patients from greater depression of CMR to higher levels. They noted that the symptoms changed from those associated with the more profound depression to those with smaller decreases of CMR and vice versa, for after they had metabolized the small amount of glucose administered, CMR would fall again and more profound levels of CMR were again associated with the signs noted in deeper hypoglycemia. These results were published in 2 papers.

While Dr. Frostig was Dr. Himwich's guest, the latter received an invitation from Tom Douglas Spies to study brain metabolism in patients with pellagra and Dr. Fros-

tig was one of the group to go down to Birmingham. The work there resulted in at least 2 publications, one with Tom Spies and Dr. Himwich on CMR and the other chiefly on the clinical side with Tom Spies alone.

Dr. Frostig was offered a research position by Dr. Langley Porter, Dean of the Medical School at the University of California. This was as a result of Dr. Aaron J. Rosanoff's invitation to introduce insulin treatment in the California State Hospital system.

The premature death of Dr. Rosanoff and the outbreak of World War II interfered with the plan to modernize the treatment of acute mental disorders. This was already under way at Camarillo, Patton and Stockton State Hospitals. During this period in California, Dr. Frostig wrote a monograph which summarized the results of his research in insulin shock treatment. Although accepted for publication on behalf of the University of California by Doctors Bowman and Rosanoff, and later recommended to Dr. Nolan D. C. Lewis and the Masonic Fund by Dr. Adolf Meyer, the monograph was never published. Rising printing costs and a lessening of interest in insulin coma therapy were regrettable circumstances.

In 1945, Dr. Frostig spent a year in New York in order to obtain a medical license. He returned to Patton State Hospital in 1946. Unable to resume his prewar program, he resigned in 1947 to engage in private practice in Los Angeles. Here he exerted an important influence on his colleagues as a recognized scholar and teacher.

He was on the staff of the Cedars of Lebanon Hospital, taught at the College of Medical Evangelists, and was consultant in the Department of Psychology at the University of Southern California.

He leaves behind his wife, Marianne Frostig, Ph.D. in educational psychology; a daughter, Mrs. Anna Marie Miller, and a son, Thomas.

Dr. Frostig was a source of inspiration to many psychiatric colleagues in California. He acquainted us with the rich heritage of European psychiatry. Since he was a personal friend of several world leaders in psychiatry, his scientific discussions were often enlivened by delightful anecdotes about these individuals and their work. He was a kind and dedicated person, a student of the first order, but unfortunately World War II interrupted his most productive scientific activities. In this country he pioneered as one of the discoverers of electro-narcosis therapy and was considered a foremost authority and researcher in insulin shock therapy.

The foregoing factual summary of Dr. Frostig's scientific and professional contributions does not reflect adequately the warm sympathetic insightful and keen human being. To his students, patients and friends, he was always a source of great inspiration and called forth from them deep affection and loyalty. Those who knew him intimately miss him as a generous friend, a gifted healer, a stimulating colleague and a broad-visioned humanitarian.

PSYCHIATRIC AND MEDICOLEGAL IMPLICATIONS OF GENETIC AND ENDOCRINOLOGIC RESEARCH IN SEX DETERMINATION¹

KARL M. BOWMAN, M.D., BERNICE ENGLE, M.A., AND
MARJORIE MERGENER, A.B.²

In the last 3 years we have had a breakthrough in genetics and in sex determination which has greatly affected our understanding of and ways of treating a number of psychiatric conditions. This new knowledge of the human chromosomes has revolutionized some of our thinking. Until 3 years ago biologists thought that the human being had 48 chromosomes, but we now know that man has only 46(1). These chromosomes can be identified and counted only when the cell is dividing into two daughter cells. The ovum and sperm by processes of division lose one half of the 46 chromosomes and thus have only 23 (haploid). The other body cells have 46 chromosomes in the form of 23 pairs (diploid). In the ovum the 23rd chromosome is always an X chromosome; in the sperm cell it is an X half the time, a Y the other half. If the sperm cell has an X chromosome and combines with a normal ovum the resulting individual will be a normal female and the 23rd pair of chromosomes in each cell will be XX. Conversely a Y chromosome in the male will result in a normal male with an XY pair of chromosomes in each cell(2).

The fact that the sex of the newborn child is normally determined by the father and not by the mother is important to us as psychiatrists because the common misunderstanding has resulted in many women being blamed for bearing only girls. In some cases separation and divorce have resulted and in other cases women have developed severe depressions.

The problem of determining the sex of the newborn child is quite easy in the vast

majority of cases but in a few cases differentiation is not easy and mistakes are made. Certain basic concepts are necessary in understanding this whole problem. In the first place no individual is completely masculine or feminine. Anatomically, physiologically and psychologically every individual has elements of both sexes. The normal testicle secretes estrogen (the so-called female hormone) and in the normal female the adrenal cortex secretes androgen (the so-called male hormone). The developing embryo remains sexually undifferentiated for about 48 days. Primary sex differentiation, as determined by the genetic sex, develops between the 48th and 57th days. From one primitive gonad, either the cortex will develop into an ovary while the medulla (center) will regress; or the medulla into testes, and the cortex regresses. Of the two ducts of the embryo, Wolff's duct develops into the male sperm duct, and Muller's regresses in the male; and Muller's duct develops into the fallopian tubes, uterus and upper vagina in the female, while Wolff's duct regresses. At about 60 days the external genitals are recognizably differentiated; and hormones are known to influence their development(3).

We thus see that the normal individual develops the sexual organs of his own sex and suppresses the development of the sexual organs of the opposite sex, although the residues of these undeveloped parts still remain in his body. Ordinarily all this is determined by the genetic factors we have mentioned and the characteristics of the 23rd chromosome in the sperm cell.

However, a number of things may happen to prevent his normal development as a clear-cut male or female. On a genetic basis the individual may have more of the attributes of both sexes. Even if there is no hereditary cause, several conditions in the

¹ Read at the 116th annual meeting of The American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² University of California, San Francisco Medical Center, San Francisco, Calif.

mother may adversely affect the development of the fetus including the sex development, for example, hormonal tumors; German measles, particularly during the first 3 months of pregnancy; exposure to x-ray; and hormonal treatment. The genetic sex of the individual is determined at conception, but factors may occur either before or after birth which modify the sexual development. Attempts therefore have been made to determine the genetic sex of the individual (3).

One test considered reliable within its limitations is the sex chromatin test. The most common way of performing this test is to make a buccal or vaginal smear, stain these cells and study them under the microscope. A stained mass of chromatin is clearly visible in up to 70% of the nuclei of normal female cells. This has been called chromatin-positive or female chromatin pattern. The chromatin mass is present in less than 6% of normal male nuclei and has been called chromatin-negative or male chromatin pattern. It was held that the chromatin-positive reaction indicated the presence of 2 X chromosomes and that the chromatin-negative indicated a lack of 2 X chromosomes (4). Recently this viewpoint has been abandoned and Barr, in a letter in the November 13, 1959, issue of *Science* states, "The precise relationship between the sex chromatin and chromosomes is an unsolved problem that challenges the resources of cytologists." Since in some writings *chromatin* studies are equated with *chromosome* studies, it is important to emphasize that these are two entirely different studies and that there is not the clear-cut relationship between the two tests which was thought to exist.

The final criterion is the actual viewing of the chromosomes. This test is a most difficult one and can only be done by comparatively few persons who have had a great deal of experience in this work. The cells in bone marrow or skin culture are arrested and held in a phase of mitotic division and are so treated as to allow each chromosome to be distinguished and the pairs to be identified. The normal individual will show 23 pairs of chromosomes; the last pair, the sex chromosomes, will distinguish the sex.

An XX pair normally characterizes a female and XY, a male (5).

We now know that a number of variations in numbers and types of the chromosomes may occur with profound effects on the individual. The following table indicates possible variations of the sex chromosomes and the conditions that will result:

POSSIBLE VARIATIONS OF SEX CHROMOSOMES (23RD PAIR)

BOTH CHROMOSOMES NORMAL

1. X-X Normal Female
2. X-Y Normal Male

MALE CHROMOSOME ABNORMAL

3. X-XY Klinefelter Syndrome
4. X-O Turner Syndrome

FEMALE CHROMOSOME ABNORMAL

5. XX-X Metafemale
6. XX-Y (Same as 3.)
7. O-X (Same as 4.)
8. O-Y No Case Known

BOTH CHROMOSOMES ABNORMAL

9. XX-XY No Case Known
10. XX-O Normal Female
11. O-XY Normal Male
12. O-O Probably Inviabile and Early Abortion

We have listed 12 possible variations in the combinations of sex chromosomes and attempted to predict the results. Three of these have never been reported: numbers 8, 9 and 12. Some workers recently claimed that the sex chromosomes can be identified as coming from the male or from the female. We have accordingly drawn up these possible 12 combinations showing the female sex chromosome (or chromosomes) on the left and the male chromosome (or chromosomes) on the right. It will be noted that numbers 6 and 7 derived from abnormal female chromosomes yield the same final combination as do numbers 3 and 4 derived from abnormal male chromosomes. We will be interested to find out whether a process of differentiation between the female and male sex chromosomes will show that these conditions actually occur and whether this may even explain the fact that we do not always get the same chromatin pattern in all cases of Klinefelter's and in all cases of Turner's syndromes.

We have written to Dr. C. E. Ford of

England regarding these 12 different combinations and raising the question of two abnormal gametes combining; and referring to the mention by Hungerford, *et al.* of the possibility of an XXXY genotype (September 1959 issue of the *American Journal of Human Genetics*). Dr. Ford was also asked if he would care to speculate as to the likelihood that homosexuals, transvestites and complete sex inverters might belong to any of these abnormal groups. Dr. Ford was kind enough to answer our letter as follows :

COPY

MEDICAL RESEARCH COUNCIL

RADIO BIOLOGICAL RESEARCH UNIT

Harwell,

Didcot, Berks.

23rd November, 1959

Dear Dr. Bowman :

Thank you for your letter of November 12th. The XXX female type has now been identified. Only one case has been found as yet and this was reported in a recent issue of the *Lancet* (September 26th.) by Jacobs and her colleagues at Edinburgh.

You are quite right regarding the possible occurrence of the 4 additional forms : I did not mention them because their expected incidence would be so low. Actually the XXO and XYO types should become normal female and male respectively. The OO type I would confidently expect to be inviable and to lead to early abortion. On the other hand the XXXY type might well be viable although, of course, very infrequent indeed. If it *did* occur it would be a most interesting case indeed from the point of view of sex chromosome balance.

As you will read in the account of the XXX case the patient had no striking abnormality and it occurs to me that there may well be many more such cases at large in the general population. After all, if XX eggs fertilised by Y sperm make any considerable contribution to the incidence of Klinefelter's syndrome (chromatin positive)—the evidence of Nowakowsky and his colleagues suggests that they do—there should be an almost equal number of XX eggs fertilised by X sperm to give XXX individuals. As to the likelihood of the XXX cases or the anticipated very rare XXXY cases behaving as homosexuals or transvestites I do not think that present evidence provides sufficient basis for offering an opinion.

I fear that what I have said in this letter may not be of very much value but if you

wish to quote anything I have said by all means do so.

Yours sincerely,

s/ C. E. Ford

We now understand a number of conditions and can treat them effectively. Two conditions have been regarded as sex transformations : Klinefelter's and Turner's syndromes. Klinefelter's syndrome is that of a sterile male usually with some degree of gynecomastia and with small testes. In most cases he can have erections, ejaculations and a normal sex life. Some are eunuchoidal males ; a minority also have gynecomastia. A number of these patients have been discovered only because they sought medical advice about infertility. Many patients with Klinefelter's syndrome were thought to be genetic females who had been transformed into imperfect males. This was due to the fact that this group (contributing about two-thirds of the cases of Klinefelter's syndrome) had a positive chromatin pattern (incorrectly called "female chromatin pattern"). The study of chromosomes has, however, cleared this up. These cases have 47 chromosomes, the 23rd pair has an additional X so that the combination is XXY(6). Klinefelter's syndrome therefore is no longer considered a case of sex reversal from a female into an imperfect male, but as a condition in which a male has developed imperfectly because of a chromosomal abnormality. It is associated with other congenital anomalies, of which mental retardation and renal abnormalities are the most common.

Two cases of chromatin-positive Klinefelter's syndrome with characteristic symptoms were reported in identical male twins with 9 normal siblings(7). At age 15 both boys, eunuchoid in appearance, failed to develop male secondary sex characteristics and Twin A's breasts began to enlarge. Testicular biopsy on Twin A, who had had nocturnal emissions, showed some spermatogenic activity; none had occurred in Twin B. The first twin underwent plastic surgery on his enlarged breasts, preceded and followed by testosterone therapy. He showed no interest in girls and his "behavior impressed several observers as effeminate." Twin B's personality pattern "revealed anxiety and fear associated with an awakening sexuality."

Turner's syndrome is the reverse of this. The syndrome is usually characterized by failure of the ovaries and of secondary sex characteristics to develop and other congenital anomalies including shortness of stature and webbing of the neck. Some variations in the symptoms have been seen. Breast development, spontaneous menstruation and ovarian development have been reported(8). Girls with this condition, as far as known, are always sterile. About 80% of these cases are chromatin-negative and this led to the concept that they were males changed into imperfect females. We now know that the condition is often associated with a lack of the Y chromosome so that in this group the individual has only a single X chromosome and it is represented as XO instead of the diploid XX which the ordinary female has. According to Ford and co-workers "she is a female with an abnormal genotype."

An atypical case of chromatin-negative Turner's syndrome was followed at the University of California Hospital for over 10 years. Though her parents and 2 sisters were normal, the girl, born in 1945, had a rudimentary uterus, atrophic ovarian tissue, a webbed neck and other stigmata of Turner's syndrome. At age 12 some pubic hair appeared but at age 15 her appearance was still that of an extremely short, sexually immature girl. Pituitary growth hormone to encourage maximum growth was given and estrogen therapy planned. The pediatrician frequently consulted the parents about the patient. When the patient was 13 she and her mother were seen individually for 6 hours of psychotherapy by the University of California pediatric mental health unit over a 6-week period. While at first described as somewhat antisocial, belligerent and sensitive about her size, she expressed her desire during the therapy to be a bride and a mother, or a nurse or nun. After psychotherapy the patient was described as apparently happy and socializing well.

We conclude, therefore, that legally a patient with Klinefelter's syndrome is a male and that it is psychologically important for him to consider himself a male and for those about him to do so. Treatment may consist of bilateral simple mastectomy best performed by a skilled plastic surgeon and, if eunuchoidism is present, administra-

tion of androgens. A patient with Turner's syndrome is legally a female and it is likewise important for the patient and others to consider her a female. Turner's syndrome may be treated by the cyclic administration of estrogens to stimulate the growth of female secondary sex characteristics and to produce some uterine bleeding. A few patients have menstruated spontaneously. A psychiatric evaluation should be done in all cases and psychiatric treatment is frequently indicated. A legal consideration might be the question of annulment or divorce if the individual knew at the time of marriage that he or she was sterile.

Another interesting condition is the meta-female(9), sometimes called superfemale, which is associated with an XXX set of sex chromosomes so that the individual has a total of 47 chromosomes. Only one case has been reported to date(10), a 35-year-old woman sexually underdeveloped who stopped menstruating at the age of 19. She had infantile external genitals, underdeveloped breasts, and a high (71%) proportion of chromatin-positive cells. She was of below normal intelligence.

A possible variation would be the individual born by parthenogenesis, or virgin birth. It is recognized that this can occur in other mammals, fatherless rabbits having been experimentally produced (Pincus)(11). It does not appear inherently impossible in man. If such a condition did occur there would possibly be a haploid nuclear structure with only a single set of chromosomes, including only a single X chromosome. Such an individual would be female in apparent sex and would presumably be sterile. It would be possible to determine such an individual by two tests: only blood groups derived solely from their mothers would be found and a skin graft from the daughter to mother should survive. Attempts have been made, particularly in Great Britain, to find such haploid individuals but careful examinations have always indicated that the cases under study were not the result of parthenogenesis (Platt, Stratton)(12). However, Pincus points out that parthenogenesis in rats with production of haploid offspring, does not result in any viable progeny. All his rabbits that survived had diploid nuclear structure.

He concludes from this: "Evidently the formation of a double set of chromosomes is essential to produce even an approximation of normal parthenogenetic development."

Although cases of eunuchoidism are usually correctly identified as to sex, it seems that a brief discussion of this condition should be given. A whole group of individuals, both male and female, are imperfectly developed sexually and at puberty fail to develop the normal secondary attributes of their own sex. One of the most frequent causes is a failure of the pituitary gland to secrete the sex stimulating hormones. Another is failure of the gonads to function normally. The condition occurs occasionally in families but in some cases it is not known whether the defect was of the gonads or of the pituitary gland. Biben and Gordan (13), however, report 5 instances of eunuchoidism of pituitary origin in two families in which sex hormone treatment successfully produced genital development. Some boys with undescended or partially undescended testicles may respond quite fully to endocrine treatment and their testicles will then descend. In eunuchoid males the penis is commonly very small. Many of these boys show marked disproportionate growth in their long bones (arms and legs). Eunuchoid girls are likewise tall and usually continue to grow beyond the normal age. In the girls the uterus fails to mature and at puberty other sex characteristics do not develop. Again, the appropriate sex hormones bring about normal maturation in almost all cases.

While the cause in most cases of sexual precocity is unknown, congenital adrenal hyperplasia, the same genetic defect which produces female pseudohermaphroditism, often produces premature sex development in boys. Hypothalamic tumors produce this condition in both sexes and other known causes are tumors of the ovary in girls or tumors of the testis, adrenal cortex or the pineal in boys. It can start as early as 2 years and develop rapidly, with puberty attained before age 9 or 10.

These children offer various medicolegal difficulties. The sexually precocious boy may be kept out of school because parents fear to have their children associate with him. The sexually precocious girl may be-

come pregnant at a very early age, like the Peruvian (14) girl, who began menstruating at 8 months and at 5½ years gave birth by Caesarean section to a 6-pound boy.

A fraternal twin boy, with a normal sister, was hospitalized at the University of California Hospital and at Langley Porter Neuropsychiatric Institute intermittently over a 3-year period because of his sexual precocity, for which no cause was found. Sexual development began at one year; by age 8½ he was sexually mature and his bone and hormonal ages were well into adolescence. Though his IQ was substantially below normal, the psychologist emphasized that his retardation could be a result of his earlier enforced isolation, when his mother, under neighborhood pressure, fenced him in a 4' x 10' yard. The public school refused to keep him because of his boisterousness, and his mother was unable to handle him without his father, who had left the home. At that time the patient was hospitalized 6 months at Sonoma State Hospital for observation and transferred to Langley Porter Neuropsychiatric Institute for treatment.

The boy, a lively, boisterous and sometimes destructive child, improved in his relationships with the doctors and other personnel, probably the result of psychotherapy. Even at the hospital, however, he was sometimes treated more like an adolescent than a boy age 6½. After 3 months his mother decided to take the patient home and at the latest report he was attending school apparently with success.

These children, though they may look like adolescents, are still children to be treated as such; usually they are not over-sexed, but merely prematurely developed. By puberty their growth will have stopped so that by age 18 they are actually shorter than most boys and girls of their age. If these children are handled intelligently during the period of precocity, they should become normal, though short, adults.

Mistaken identification of the infant's sex may occur commonly in pseudohermaphroditism and in true hermaphroditism. Female pseudohermaphrodites have ovaries, with some male characteristics. The female complex of chromosomes is apparently normal; but an excessive secretion of androgens, most commonly from the overdeveloped fetal adrenal cortex before birth,

is one factor in causing the male characteristics.

In adrenal cortex overdevelopment, caused by a recessive gene, according to Crumbach and Wilkins (15), the infant may or may not be recognized at birth as a female. As virilism progresses, the clitoris enlarges to resemble a penis, body hair appears early, and at puberty a beard grows and the voice deepens, but breasts and menses do not develop. Crew (16) cites evidence to strongly suggest that 1 in every 400 males is "in fact a completely masculinized female."

With the discovery of cortisone in 1950, which suppresses the excessive secretion of androgen by the adrenal cortex, the individual treated in the early stages can develop into an essentially normal female and virilism is thus prevented. Normal pregnancies in women with congenital virilizing adrenal hyperplasia who were treated with cortisone have been reported. There is no theoretical reason why such pregnancies cannot occur in these women if their condition is treated.

A female pseudohermaphrodite with adrenal hyperplasia raised as a boy was followed at the University of California Hospital. The child, born in 1946, appeared essentially female except for a large clitoris which continued to enlarge and vulva which grew to resemble a scrotum. Her parents decided to raise her as a male and the necessary surgery was performed. By age 8 the child's breasts had begun to develop, 3 or 4 episodes of vaginal bleeding had occurred and the kidneys had become inflamed several times. A panhysterectomy was performed after consultation with the parents, who still wanted to raise the child as a male. In 1957 the child was described as a feminine-like boy of slender build. A year later the whole family was seen by the pediatric mental health unit for a course of psychotherapy; in 1959 the child was described by the father as "all boy." His doctor noted at that time that he was dating and was interested quite normally in girls.

Lisser and Escamilla (17) reported the case of a boyish-looking muscular child with abundant pubic hair and thick, protruding phallus (really an enlarged clitoris), first seen at the University of California at age 3. At birth, because of the confusion about sex assignment, the child had been registered as a male. The cell chromatin pattern was positive; an ex-

ploratory operation showed a normal-appearing uterus, tubes, ovaries and a rudimentary vagina. The parents then decided to raise the child as a girl and changed the masculine name to a feminine one. Cortisone therapy was begun and surgical construction of a functioning vagina was planned. At last report, efforts to legally change her name were being made.

Rosenwald, *et al.* (18) administered psychological tests before and after clitoridec-tomy, to 5 female pseudohermaphrodites, one of whom had been raised as a boy, up to the time of surgery. None of the children showed significant psychopathology before or after surgery, including the child whose sex was changed. In this case both the mother and the child had been seen in psychotherapy and the family unit appeared to be stable.

Male pseudohermaphrodites have female characteristics in varying degrees, from a small phallus and some degree of breast development, to the extreme of appearing as a normal, though non-menstruating woman, with breasts, external female genitalia and vaginal canal (usually a pouch), but often with sperm ducts. The excessive secretion of estrogen by the testes in the abdominal cavity or in a hernial sac causes feminine development. The high familial incidence of this condition suggests a genetically determined disorder. Because of the danger of malignancy the testes should be removed.

Goldberg and Maxwell (19) reported probably the best-known case of testicular feminization which occurred in a healthy, apparently normal girl of 19 years who came to the University of California Hospital complaining of amenorrhea. The girl had abnormally long arms and legs, conspicuously large breasts, small, though normally formed, external genitals, a short vaginal canal and a clitoris which was only a dimple. Sex hair was absent. She was described as an affectionate person who enjoyed the attention of men, but who had always felt herself somehow different from other girls. Since the patient planned to marry and wanted plastic surgery, exploratory surgery was performed and two gonads identified as testes were removed. Following the operation she was described as "more than ever anxious for marriage" and "cheerful, happy and full of vitality." At last report the patient had been married, divorced and remarried.

The true hermaphrodite has elements of both sexes, both testicular and ovarian functioning tissue, but not active sperm and egg cells. So far, as reported, no evidence of chromosomal imbalance has been found. Two instances of two true hermaphrodites in the family support the theory of a genetic cause. Money and coworkers(20) studied 12 cases of true hermaphroditism and found a chromatin-positive pattern in 8, a chromatin-negative in 4.

Historically, these persons were in many countries allowed to decide on their sex but must thereafter stick to their decision. The commonsense way is for the physician to consult with the parents and arrange for necessary surgical and medical measures.

True hermaphroditism in siblings apparently male was reported by Clayton, *et al.*(21). The 2 boys, age 16 and 7, had chromatin-positive cell nuclei, complete hypospadias without cryptorchidism, and the older one had normal male puberal changes except for small and insensitive testes. In the older boy a biopsy showed that the testes contained ovarian tissue; scrotal exploration and testicular biopsy on the younger child also showed ovarian tissue. Except for the congenital abnormality of his penis, which was repaired at 4 years, and a eunuchoid body build, the 17-year-old was in excellent general health and development and was said to be a psychologically well-adjusted male. The younger boy was also in good general health and showed normal growth and development. The authors concluded that the identical gonadal differentiation of the siblings proved the defect to be of genetic origin. The children had a normal 12-year-old brother and no other familial instances of abnormal sex development could be found.

All this is of great interest to psychiatrists because the finding of individuals who were conceived as members of one sex and developed into the opposite sex may offer grounds for all sorts of further study. Questions have been raised as to whether homosexuals might belong to one of the groups of intersexuality. Attempts have been made to link up the sex chromatin pattern with the sex behavior. The few studies made so far do not show, however, that male homosexuals tend to have a chromatin-positive pattern, nor do female homo-

sexuals tend to have a chromatin-negative pattern.

Some transvestites claim to have no homosexual desires and have never engaged in homosexual acts; others vary from ambisexuality to complete homosexuality. A few are commonly called cases of complete inversion or transsexualism. A study, by Barr and Hobbs(22), of 5 male genuine transvestites showed the nuclei of a typical chromatin-negative pattern, and it was therefore "inferred that these persons bear the male XY sex-chromosome complex." Two Czechoslovakian investigators, Raboch and Nedoma(23), found that 35 of 36 men with a chromatin-positive nuclear pattern had underdeveloped testicles. They then examined 9 men with underdeveloped testicles from a group of 194 homosexuals. They concluded, since 6 of the 9 had a chromatin-negative pattern, that a chromatin-positive pattern in homosexual men would be coincidental, not causal; and that testicular androgens were the prime factor affecting "the development and course of sex life . . ." Davidson and Winn(24) conclude that "chromosomal factors play little part, certainly in transvestism and homosexuality, and the nuclear sex is not at variance with the anatomical sex in the vast majority of cases . . ." They cite, in addition to the 2 sources quoted above, a study by Wiedemann.

It is also of interest that some pseudohermaphrodites have been raised as members of the unpredominant sex. Careful studies by Money, *et al.*(25) indicate that individuals over age 2 are likely to have great difficulties if attempts are made to change the sex role. In their excellent articles they point out 7 factors to be studied in deciding to which sex an individual should be assigned. These are:

1. Assigned sex and sex of rearing
2. External genital morphology
3. External accessory reproductive structures
4. Hormonal sex and secondary sexual characteristics
5. Gonadal Sex
6. Chromosomal Sex

Patients showing various combinations and permutations of these 6 sexual variables

may be appraised with respect to a 7th variable:

7. Gender role and orientation as male or female, established while growing up.

From their studies of over 100 cases they concluded that by about age 2 the individual has identified himself clearly as a member of one sex or the other, and it is usually disastrous to attempt any change after that identification has occurred. They recommend, "in the case of neonatal and very young infant hermaphrodites . . . that sex be assigned primarily, though not exclusively on the basis of the external genitals and how well they lend themselves to surgical reconstruction in conformity with assigned sex," and possible endocrine treatment.

On the other hand, Rosenwald, *et al.* (18) from their observations of sex change in a 6-year-old female pseudohermaphrodite raised as a boy and other cases followed in their clinic, stated that "under favorable circumstances change of sex can be made after the establishment of gender role without resulting in a confused patient inevitably destined to severe emotional disease." Psychological disturbances were considered not inevitable, but a result of an inherent weakness in family structure. Although reassignment of sex is inadvisable in any hermaphrodite beyond the infantile age period, female pseudohermaphrodites with adrenogenital syndrome who have been reared as boys, because of an original diagnostic error, "should be individually evaluated with regard to possible change of sex assignment."

Cappon and coworkers (26) list 6 variables of sex: genetic (chromosomal); gonadal; endocrinological; body habitus (appearance); genitals; and secondary sex characteristics. Since they emphasize the close correspondence between the psychological and the body sex, one may infer that the individual conforming to 4 of the 6 equally weighted criteria for one sex would be assigned to that gender role. This method has been much criticized.

Stoller and Rosen (27) stated that neither the somatic sex nor the early identification of the patient with one sex is all important. "The essential criterion is the strength of the patient's identification with one sex or the

other." Two British writers, Davidson and Winn (24), consider that, within certain limitations, nuclear sexing indicates the genetic and gonadal sex and is useful in assigning the individual to a suitable sex role, but often the anatomical sex and the mental outlook "are even more important factors in making a wise decision."

In our opinion, no laws should be at present enacted regarding the sex determination of pseudohermaphrodites or true hermaphrodites. In the case of a young child, the physician should decide on the basis of medical knowledge and the family's wishes; the patient himself should be consulted if old enough. It is better to leave the lawbooks uncluttered with specific statutes and to leave room for the use of medical advances and the physician's judgment.

SUMMARY AND CONCLUSION

This paper has discussed some of the latest discoveries in genetics and in endocrinology and their psychiatric significance. We now know Mongolian idiocy is due to an abnormal condition of the 19th alleles and that it may be associated with Klinefelter's syndrome. It seems likely that a whole series of psychiatric conditions will soon be linked up with disorders of the chromosomes. We realize the importance of the sex hormones. Both the androgens and estrogens are composed of numerous different substances. We do not know the potencies of each one of them nor have we adequate knowledge to correctly quantitate some of them. These are only two of many illustrations that might be given. This spectacular breakthrough is just beginning and the next 10 to 20 years will see still greater additions to our knowledge.

After this paper was presented, a basic question was raised by two articles (28, 29) in *Lancet* for July 16, 1960. The first article reported 2 cases of true hermaphroditism. "The basic diploid chromosome number in each is 46 and the sex chromosome constitution is interpreted as XX. In one patient 18.5% of cells had a chromosome count of 47. Despite the presence of a testis in one case and an ovotestis in the other, no Y chromosome was present." The second article reported one case of true hermaphroditism with 46 chromosomes and "the chromo-

somal constitution was found to be XX, indicating female sex." It cites 2 articles published a few months previously, each of which reported one case of true hermaphroditism with the sex chromosomes being XX. All this material raises a basic question as to whether the Y chromosome is necessary for the presence of a testis or an ovotestis.

THE COMMON FRONTIERS OF PSYCHIATRY AND LAW¹

HAROLD D. LASSWELL, Ph.D.,² AND LAWRENCE ZELIC FREEDMAN, M.D.³

We want to discuss those regions of personal distress and public disorganization which lie within the necessary and legitimate boundaries of both psychiatry and law and which are not yet fully explored. In the spirit of our title we will seek to identify and corral some of the common problems now ranging tantalizingly outside the borders of scientific law and social order. Later we will suggest a structure within which this initial foray may be extended in time and in legal, psychiatric and political significance.⁴

After tentative and rather slow beginnings, American universities are in the midst of rapidly expanding programs of collaborative undertakings between psychiatry and law. Mainly, these are concerned with the initiation and development of courses for the training of law students in the elements of psychiatry and behavioral science as they apply to the law. Several law schools including Yale(1), the University of Pennsylvania(2), the University of Chicago(3), Temple University(4) and other academic centers are now experimenting with teaching methods and preparing teaching material for this purpose(5). Less advanced are plans for programs of joint research. Already, however, a few research units in psychiatry and law have been organized and new ones are in prospect. Our emphasis today will be on implementation of this phase of the collaborative efforts(6).

It is our thesis that, hopeful as are the beginnings which have been made in law schools and departments of psychiatry in

our country—even in anticipation of their future contributions—no program thus far undertaken or planned is responsive to the range, significance and urgency of the problems involved. We therefore propose that this national problem, affecting as it does our most essential personal and community interests and values, must be approached on a commensurate scale.

It is appropriate, therefore, to review some of the experience we have already gained in joint ventures of this kind, and to propose a map that provides a sketch of what appear to be the lines of special promise. In so doing we shall perforce give some attention to the value assumptions and goals of the professional groups involved, and consider the proposed alternatives in the light of developing trends and projections, and of behavioral and psychiatric findings to date. We will suggest how these trends may be fused in a research institute for carefully planned and integrated long-range investigation into these common problems.

Although the range of challenging questions is enormous it is encouraging to be able to say that some collaborative work has already led to discernible results. The new intermingling of research-minded lawyers and psychiatrists is producing a common frame of reference whose potential significance for mental health as well as for community policy is far-reaching. We shall presently refer to some representative bits of research; but it would give a distorted image of these developments to lay too much stress upon present contributions.

In an earlier symposium with us, our late colleague, Professor George Dession(8, 9, 10), a pioneer in the collaboration of psychiatry and law, succinctly epitomized our common interests as being concerned with the "two areas of social process in which individuals seem to experience exceptional difficulties in the pursuit of their objectives."

The psychiatrist is rare who does not, very soon after he undertakes treatment, discover a not insignificant range of unde-

¹ This paper was written with the assistance of the Foundations Fund for Research in Psychiatry. Read at the 115th annual meeting of the American Psychiatric Association, Philadelphia, Pa., April 27-May 1, 1959.

⁴ We wish to acknowledge the stimulation of discussions with members and consultants of the Committee on Psychiatry and Law of the Group for Advancement of Psychiatry while Professor Lasswell was Consultant and Dr. Freedman was chairman.

tected illegal activity, not merely fantasied or anticipated but actually carried out by his patients, including those who come mainly from ostensibly conformist middle and upper class groups. And, indeed, only the most insensitive lawyers and counsellors remain unaware for long that legal actions undertaken by or against many of their clients are reflections of essentially psychiatric problems. These could be treated most efficiently and justly with a proper and adequate understanding of the sub-legal and sub-rational conflicting motivations expressed by them. Legal organizations may be the principal recruiting agency of psychiatric patients from the depressed socio-economic groups. In an eastern state about one quarter of the patients from the most socially and economically deprived groups who had been seen by psychiatrists had arrived there through the intervention of police or the courts. Further, the psychopathological symptomatology of this group was likely to be expressed in deviant or provocative interaction with the community (11, 12). If we thus combine the social impact of the lower class patients who act out their psychopathology so as to be caught and labelled "criminals" with our more socially favored patients whose preconscious antisocial tendencies invade the social fabric more insidiously but more effectively, the significance of this frontier of common legal-psychiatric concern becomes self-evident (13, 14).

The broad scope of research in the field of psychiatry does not need to be dwelt upon. All manifestations of mental disease are its province, and its investigation probes into the problems of individual and collective diagnosis, prognosis, and therapy and searches in particular for the factors affecting the etiology and course of the disease process. As a physician, the psychiatrist's dominant articulate value is life and health. There are, however, social demands upon him concerning which the profession is far from of one mind, or comfortable. These range from the question of the use of his knowledge for purposes of crime detection (*e.g.*, narcosis; hypnosis) (15, 16, 17), to its use for inter-nation destructive purposes, for example, psychological and biological warfare. Somewhere intermediate is the

problem of their implementation with the aim of promoting or achieving less debatable social or national political goals.

Several psychiatric projects are already engaged in gathering data about the frequency of occurrence in communities of various size and composition not only of neurotics, psychosomatic cases, and psychotics (17, 18), but also of psychopathic characters—the recidivist criminals of our culture. Psychiatrists have participated to a very limited extent up to the present in the study of the first steps that often lead to full-scale court action in juveniles and adults.

As a biologist and medical specialist, the psychiatrist was early concerned with those organic changes which might catapult an individual into psychopathology of a personally distressful or socially harmful nature. Organic causes range from feeble-mindedness on an anatomic or physiological basis to brain disease, toxicities, physical degenerative changes, and psychosomatic illness arising from predominantly psychic stimuli. Certain tentative studies would seem to indicate that there are empirically observable and measurable correlations between physical illness and social delinquency (19). Reports of those careful and able investigators, the Gluecks (20, 21), indicate a positive correlation between particular body types and incidence of juvenile delinquency. Intensive and specialized investigation into these somatosocial delinquencies would therefore appear to be one of the proper functions of the psychiatric member of a research team concerned with antisocial behavior.

Many of the conventional techniques and areas of psychiatric research lend themselves with little distortion to investigation of these compelling social psychiatric questions. For example, the wards of a mental hospital can provide rich opportunities for the investigation of power operations, loci of decision-making, and factors affecting those decisions which may have profoundly deprivational impacts. Not only learning and rewarding techniques, but also retribution, imposition of deterrents, and efforts at rehabilitation (the classical triad of criminal law) are applied daily in large mental hospitals. On the side of the

patients, this interaction involves a wide variety of character types and of symptomatic deviation. On the side of the doctors, who act as judging and decision-making figures in these hospitals, there is a comparably broad range of personalities, motives, and objectives. Stanton and Schwartz (22) Caudill *et al.* (23) and others have already made important preliminary observations; thus enough empirical data exist for the development of relevant and heuristically promising hypotheses. There are sufficient opportunities in the course of the daily hospital activities for "experimental" observations of the effect upon future behavior of decisions which implement either punitive or rewarding responses.

The focus of legal research is the community-wide process of authoritative decision. For *argumentative purposes* research has the relatively modest role of discovering precedents or "facts" likely to influence the judgment of tribunals. For *scientific purposes* the "arguments" and the "facts" become part of the phenomena to be explained. What factors account for the acceptance or rejection of proposed statutory prescriptions by the legislature or the electorate (*e.g.*, fluoridation) (24)? For the invocation or failure to invoke a provision in the formal code on the part of law enforcement officers (*e.g.*, blue laws)? For the acceptance or rejection of interpretations by administrators, courts, juries (*e.g.*, the doctrine of the *Durham* case) (26)? The effect of formal requirements upon conduct, and especially of sanctioning measures (*e.g.*, recidivism)?

Within traditional legal court and pedagogical procedures, there exists ready-made opportunity for research. For example, law schools frequently adopt a role-playing procedure as a training device which, to a remarkable degree, succeeds in integrating the factual context of an actual or hypothetical case with freedom of interpersonal interplay. Such so-called moot court cases, properly studied by qualified teams of psychiatrists, social scientists, and lawyers, may provide data to improve judgment about the most efficient way to permit the presentation to the court of the total relevant picture of personality stress and social strain. Indeed, a comparable technique is

proving its effectiveness in the University of Chicago study of small group interaction in a jury trial (27).

Experiments may be designed to explore the effectiveness of "memory" under these trial conditions and to test procedural changes in which the psychiatrist is able to communicate his best factual estimates without attempting to transmute them into terminology employed in legal doctrine.

Even these brief and inadequate reminders of the distinctive frames of research reference among psychiatrists and lawyers suffice to identify many areas of overlapping interest. On the one hand, a detailed knowledge of the formal and effective decision institutions of the community is essential if we are to uncover pertinent information about the degree in which legal arrangements increase or decrease mental disease or affect its form and content. On the other hand, psychiatric findings and methods of clinical study may be of far-reaching importance in explaining, or considering, the consequences of community decision on general issues or concrete cases.

A word on the impact of legal process upon mental health: The established practices of arrest, detention, arraignment, provision of counsel, handling of release on bail, investigation, assigning of judge, fixing of date of trial, demeanor of judge, mode of examination—to go no further—may, upon combined psychiatric and sociological inquiry, prove to be unnecessarily anxiety producing. These practices may be so disruptive of crucial family relationships, so damaging to self-esteem, and so shocking to standards of justice embodied in the super-ego, that they inflict the precipitating and necessary cause for severe and irreversible psychic damage. Within a wider community framework, if these practices are demonstrated to be relatively confusing and hence unenlightening to the reading public, demoralizing to the livelihood and competence, and disillusioning to faith in democracy, it may become clear that their deterrent effect is the reverse of that intended.

In a word, if we examine the total "value impact" of legal practices with the armory of psychiatric and behavioral instruments now available for the study of any detail-in-context, it is practicable to discover the

degree to which legal practices have positive or negative impacts upon the psychiatric health (well-being) and other values of individuals and institutions. This means that we sample how legislators, executives, administrators, the police, judges, and other officials (and official doctrines and operations) affect the emotional integrity and the total value position of others (and are themselves affected) (28).

At this point we turn more specifically to promising lines of collaborative research, hoping to amplify and modify the conceptions touched upon thus far. For convenience, we classify the proposed lines of study in 6 groups: (A) Studies of the participants in the legal process; (B) of the procedures by which legal administrative decisions are arrived at; (C) of the sanctioning and corrective methods employed by the community to accomplish its objectives; (D) of the factors that affect the degree of conformity or non-conformity to legislative policies (authoritative prescriptions) of the community; (E) of the process of struggle and agreement, especially in the world community; (F) of professional education and development.

Every individual and group that plays a role in the decision process of every community is a potential subject of investigation by the use of the hypotheses and methods of psychiatry and the social sciences, and oriented toward the principal questions pertinent to legal inquiry. We concentrate upon two groups briefly, the "recommenders" and the "invokers," in order to provide a somewhat specific picture of the possibilities (25, 29).

Not much is known about the psychological identity of persons who take the lead in demanding legislation whose primary or sanction provisions stand out, in terms of community norms, as either remarkably coercive or restrictive, or as notably "tolerant" or permissive. We are almost ignorant of the epidemiology of pressure groups and individuals who are strikingly coercive or permissive on sanctioning measures such as capital punishment, prolonged imprisonment, deportation, sterilization (and so on); and who are active in support of extreme and violent policies on such topics as school and social segregation, intermarriage among

ethnically distinct individuals, divorce, obscenity in the contents of mass media of communication, religious worship in the public schools, loyalty oaths, regulation of trade unions and business monopolies, and alcohol consumption. These questions are all controversial at various times and places in our civilization; and psychiatrists have come to realize that they may provide congenial forms of ego-syntonic role-taking as defenses against expressions of the inner tension of the mentally ill, or may be social reflections of ego-dystonic conflicts and compulsions.

It is obvious that even if these psychic realities are better studied they do not necessarily determine the social validity of the conflicting opinions themselves. Even an extreme position, or willingness to play an active agitational part in public life, does not warrant an insinuation of disease. However, it cannot be denied that the accumulation of psychiatric knowledge has often connected the *different* with the pathological. Enough miscellaneous data, amply augmented by a steady stream of innuendo, is now in circulation to justify a serious attempt to put the whole problem in balanced perspective. It may even diminish somewhat the alleged tendency, for example, to assume that whatever is not "conservative" is "crazy."

Such an enterprise is peculiarly suitable to the joint efforts of lawyers and psychiatrists. This is especially true when we study not only the "recommenders," but the "invokers" of existing statutes, doctrines and other formally authoritative prescriptions. What motivations energize public officials who are extraordinarily zealous in "carrying out the law"? What are the motives and characteristics of unofficial members of the community who formally take the initiative in alleging, whether falsely or accurately, the criminal violation of which sorts of community rules? There has already been psychiatric concern, and clinical research, directed at the so-called litigious, frequency paranoid, personality. How many of these complaints, when investigated by competent teams, would prove to have a factual basis, whether or not the complainants press them? There is also the converse problem. What are the qualities

of those considerable numbers of passive, possibly masochistic, individuals who suffer undoubtedly illegal deprivations (e.g., assaults) without invoking legal protection?

The way that judges or juries solve the problems with which they are presented depends in no small degree not only upon what comes to their conscious focus of attention during the litigation, but also the myriad preconscious stimuli which unknowingly impinge, and the unconscious (endogenous) factors to which they respond but do not attend. And not *all* that is brought into the *conscious* attention field is successfully guided by the "procedures" which bear this label in legal language. In general, there has been insufficient concern and hence knowledge about the psychological effect of the procedures which relate to the persons permitted to be present in the courtroom, or which formulate limits upon how the parties present their claims and justifications through counsel (including arguments and evidence); or which seek to determine how the final acts of deliberation and commitment are arrived at.

It is essential to realize that in terms of effect any given decision is oriented toward the *future* and toward the *community as a whole*. The immediate response of judge or jury has an immediate effect upon the total value position and especially the emotional well-being of the immediate parties. But the conspicuousness of this impact should not distract us from recognizing that all other participants are similarly affected. This is not only true of counsel for the defense and prosecution, but for the witnesses, the judge, the jury, the immediate spectators, and for the community outside the courtroom.

However, these *immediate* effects are only some of those that follow a decision outcome, and hence are presumably brought to the notice of decision makers when they allow themselves to be guided by the comprehensive value-objectives of a body politic. Relevant considerations include: 1. Longer range as well as immediate effects upon the offender; 2. Deterrent impacts upon potential deviants from prescribed norms; and 3. Impacts upon other members of the public. The problem that challenges joint research is how to bring

psychiatric knowledge to its optimum place in the pre-decision sequence.

Clinical data derived from representative psychiatric cases, supplemented by psychiatric interview and psychological projective material, need to be studied step by step in order to develop more explicit criteria for the total involvement of psychiatrists in the case from its inception. It is abundantly evident from experience to date that lawyers and psychiatrists have been insufficiently informed of the considerations that enter into their distinctive approaches. Hence very few new procedural proposals have thus far emerged. It would of course be valuable to have other disciplines represented in these case studies, notably sociologists and psychologists (30, 31, 32).

Another feature of these case studies can be the making of estimates of the *future* result of the entire range of alternatives open to the community decision makers (police, prosecutors, court, etc.) at each step of the way. This can be especially productive when teams composed of several disciplines are included, both in the investigation of past cases and in the concurrent examination of pending cases.

Some of the estimates of future alternatives will relate almost entirely to the *defendant*. What is the probability that he will repeat the same act that he is believed to have committed in the past? For example, what is the likelihood that a molester of children will turn into a rapist within the next five years if released presently without therapy of a particular kind? Or, on the contrary with therapy what are the chances that he will abstain from any sexual offense? If the assumptions made about the future are less contingent upon estimates of *present psychopathology* than upon *exposure to specific environmental circumstances*, the critical question becomes that of judging the likelihood that the defendant, if released under various conditions, will be confronted by an upsetting environment. We use the term "upsetting" only to imply that the situation will favor the occurrence of an act that violates a norm of conduct. In our capacity as scientists, it is relevant to consider another possibility, which although formally excluded from the scope of the court, is appropriate to other pub-

lic order officials. It is likely that the defendant who is performing a mild sex offense today will turn into another type of offender, a murderer, for instance, tomorrow(33)? Questions of this kind arouse the uneasiness of lawyers, since they appear to contain an element of prior judgment; they ought therefore to be considered in detail as part of the agenda of research.

We have been referring to the specific defendant before the court and the range of psychiatric testimony that can be brought to the notice of the court by procedures. Another body of psychiatric and social science investigation can relate to *potential offenders other than the defendants*. What will be the effect upon potential offenders of adopting any specific alternative in dealing with individual defendants of various categories? Deterrence is a recognized aim of public policy in these matters, and it is plausible to believe that court procedures can be adapted to the simple presentation of expert estimates of collective results.

For purposes of systematic analysis it is convenient to add a third category to be covered by estimates referring to the future. We include *all members of the public other than defendants or potential performers of a given offense*. Under various circumstances members of the public are likely to respond to court action in ways that affect public order and psychic health. Hence experts on public response may be asked to estimate the reception likely to be given a range of specified decision outcomes. For example, if the court deals with an offender in ways that are regarded as outrageously lenient by influential and active members of the public, how will this affect the treatment received by a released defendant, as well as the status of the officials and organs responsible for public order? One outcome may be a strong demand that the legislature change the criminal code in directions that restrict the individuation of the court's treatment of offenders. Here again we are touching a topic that occasions uneasiness among lawyers. No one need deny that estimates of public response probably enter into the judgment of courts. But there is reluctance to face such matters directly for fear of undermining the degree to which courts

operate independently of political factors, or are reputed so to operate. Clearly a borderline topic of this kind is peculiarly suitable for careful, long-term, joint research. Eventually it may be regarded as practical to experiment with rules of procedure that permit estimates of public response to be made by experts.

Psychiatry and the behavioral sciences have as yet contributed little to many questions of trial process, such as proof in the adversary setting, the meaning and efficacy of traditional devices like the oath, and of the validity of newer information-gathering methods such as the polygraph "lie detector," and "truth serum" drugs(34, 35, 36). Still broader inquiry is needed into the dynamic interaction of the trial participants, the accused, the judge, the contending attorneys, the public, and the mass media of communication.

A further major line of joint research relates to measures relied upon by community decision makers to cope with deviational conduct(37). It is more obvious than ever that ordinary sanctioning arrangements, when they are not purely punitive, are primarily educative. They presuppose that an individual knows enough of the appropriate culture to learn when he is confronted by a contingent threat of negative sanction, or when he is exposed to the sanction if he takes a deliberate risk and loses. The presupposition that an individual is educated or educatable, in this sense, does not apply to some categories of people. It is one of the continuing contributions of psychiatry that it is improving the criteria by which it can estimate the future conduct of individuals under specified conditions, helping thus to identify the defendant who is not at a given time amenable to the educative impact of sanctions and hence not deterrable by them. Besides the unassimilated, who have not acquired the culture in the first place, are certain categories of psychological illness and mental defect. These are not *sanction* but *corrective* problems; and the aim of corrective measures in so far as the defendant is concerned is to reconstruct the individual's mastery of himself and the culture to a level that makes it possible for him to learn from sanctioning measures. This is consonant with the psychiatric ther-

apeutic goals of re-establishing an effective function by balance of ego-superego control of psychic functions. Further research is needed to provide firmer bases for the prediction of the relative efficacy of various alternative deterring and sanctioning methods on the individual and his community. Not enough is known about the dynamics and effectiveness of retributive, deterrent, and rehabilitative techniques in response to behavior which offends the social group. Although absolutist and often contradictory assertions are reiterated in the literature of the two professions, we have little evidence concerning whether punitive sanctions deter potential malefactors. More specifically, we do not know which legal sanctions deter what kinds of individuals from committing what kinds of antisocial acts. There is, as yet, practically no body of valid information to draw upon in selecting candidates for probation and parole, or in abetting the success of those who have been selected (39). Perhaps most important is the tentative nature of our information regarding the relationship between the informal processes of social sanctioning and the formal legal procedures, especially of the reincorporation into the community of the released offender.

In modern America the psychiatrist is being called upon to play an increasingly important part in every phase of community deliberation and action. While it is common knowledge that the psychiatrist is drawn into many criminal and civil cases and is continually involved in the activities of agencies of correction and custody, it is necessary also to recognize that he is now likely to be asked to appear before administrative boards and commissions and, speaking for himself or for an association of professional colleagues, to testify before committees of the legislature at all levels of our governmental system. Properly organized research teams are in a position to explore for the first time the total impact of a given kind and magnitude of psychiatric difficulty upon conformity and non-conformity to community norms. It is possible that one result of research will be to suggest that some of the norms of conduct prescribed in community codes are unenforced and in fact may be unenforceable due to ambi-

valent community responses to them. Scientific teams may provide the factual inventory on the basis of which codes may be kept in harmony with the fundamental objectives of public order. We suspect that revisions are likely to be indicated in some of the statutes relating to sexual conduct, for instance (41). The attempt in writing criminal codes to stigmatize as "criminal" certain forms of behavior may fail because the particular sanction fails to correspond to the moral judgment of the community (42, 43). It is at least possible that psychiatric problems may be precipitated in these cases by the individual conflict which in turn is a reflection of paradoxical and inconsistent community expectations and sanction (40, 44).

In view of the urgency of world affairs, we feel a special sense of the importance of the field of international law and relations in so far as the problems connected with these difficult issues can be given factual study. Psychiatrists have traditionally fought shy of the study of factors contributing to war and crisis, to revolutionary conflict, rebellion and riot. Yet it is obvious that our professional concern for mental health goes much further than the case by case care of individuals. We do in fact explore the collective impact of various factors upon the incidence of mental difficulty. Before the last war, the physicians of The Netherlands issued a declaration concerning war as a medical problem of research and therapy. And it must be admitted that in so far as collective, no less than individual, living is responsive to unconscious factors, the psychiatrist (and psychoanalyst) is professionally involved. The crucial issue is whether we are equipped with research methods and conceptual categories capable of being fruitfully applied to the gigantic issues at stake. Our view is that we are in position to make a beginning and that exploratory research can be productively directed to certain problems. Can we aid in identifying the situation, for example, in which the rival leaderships in a community situation, or in an institution, move toward a breaking point? Published studies of such community situations would probably serve as objective reminders to leaderships everywhere of the explosion points in human

affairs, and might exercise a deterring influence upon risk-taking under hazardous conditions. At any rate, we can hope by means of joint researches to learn more about the propensities to coerce, lawfully or unlawfully, that are found in the relations among national states as well as social classes, interest groups, and individuals. We believe that whatever we can contribute, however modest, is worth the effort (45).

No plan less ambitious than a National Institute devoted to an integrated and comprehensive attack simultaneously carried out on all phases of strategic problems common to psychiatry and law is responsive to the scope of these social dilemmata (7). In later publications it is our intention to consider some of the basic desiderata for such an institution, including its structure and function, the training and disciplinary background of its chief participants.

THE PSYCHOPHYSIOLOGIC SEQUELAE OF HEAD INJURIES^{1, 2}

ARTHUR H. AUERBACH, M.D.,³ ALBERT E. SCHEFLEN, M.D.,
RAYMOND B. REINHART, M.D., AND CAROL K. SCHOLZ, PSW

This paper is the report of an inquiry into the nature of the post-traumatic syndrome. This condition, also known as the post-concussion syndrome, occurs frequently after head injuries. It is a diagnosis made mainly by neurologists and neurosurgeons rather than by psychiatrists. The most usual symptoms are headache, dizziness, anxiety, irritability, insomnia, impairment of memory and concentration, and reduced tolerance to exertion, alcohol and heat.

The cause of the condition is not entirely clear, although it is generally believed that both physical and emotional factors contribute to it (12). Among the organic causes named are: vasomotor changes, perhaps associated with the brain stem damage (11), meningeal adhesions which produce traction on the dural sinuses (14) and effusion of cerebro-spinal fluid into the sub-dural space (10).

Emotions enter into the post-traumatic syndrome in a number of ways: 1. The head has great psychic value, and injury to it may represent an overwhelming of the ego. The headache, dizziness and other symptoms originally caused by organic damage may serve as a nucleus for a neurotic reaction (20).

2. The hope for compensation often operates unconsciously to prolong symptoms.

3. Where litigation is involved there may also be the desire for revenge, or the need for tangible proof in the form of judicial decision that one's symptoms are justified.

4. The uncertainty surrounding the post-traumatic syndrome permits the development of doubts and fears of the unknown. When the symptoms persist, the patient

often senses that what he has is not a well-defined, clearly understood condition but rather a vague one which can be variously interpreted. His contact with doctors, lawyers and others may leave him wondering whether his trouble is due to brain damage, "nervousness," or imagination. Although most patients eventually recover, it can be at a considerable cost in time, money and suffering; and a certain number remain permanently incapacitated by the post-traumatic syndrome.

METHOD

The general method employed was follow-up interview and examination of patients who had suffered head injuries. Only those injuries were included which were severe enough to result in admission to a hospital for 24 hours or longer. Forty-eight cases were found among 130 patients who had been admitted to the neurosurgical service of Temple University Medical Center because of a head injury from January 1, 1957 to October 1, 1959. Together with 2 other patients, the total number of subjects is 50, with age range from 15 to 57 years, and a mean of 31. It is not easy to say whether the patients we saw are a fair sample of all head injured subjects. Our sample may contain a larger proportion of patients with residual symptoms, since these would probably be more likely to agree to a re-examination. The interval between the injury and examination ranged from 5 to 36 months, with a mean of 12 months. In only 10 cases was the interval greater than 18 months.

The interviews were conducted by psychiatrists along the lines of the usual medical and psychiatric history. Data were recorded on a form consisting of 80 items covering both physical and emotional aspects of the injury and recovery, as well as details of the pre-traumatic life situation and personality. Examples of the variables which were inquired into are: the subject's socio-economic status; type and severity of injury; nature of the post-traumatic symp-

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² This investigation was supported, in part, by a research grant from the Office of Vocational Rehabilitation, Department of Health, Education and Welfare, Washington, D. C. The authors wish to express their thanks to Norma Scheffen, Ph.D., Max Katz, M.D. and Allen Miller, M.D., for their assistance.

³ 255 S. 17 St., Philadelphia 3, Pa.

toms; and level of adjustment following injury.

The original aim was to divide the subjects into two groups, according to whether or not they had developed the post-traumatic syndrome. The two groups would then be compared, in an effort to determine which variables correlate with the occurrence of the syndrome. However, in many cases it was difficult to decide whether or not the subject had the post-traumatic syndrome. Most patients had developed some, but not all, of the characteristic symptoms. There was quite a scattering of symptoms among the subjects, with no obvious clustering which would allow a division of the sample into groups. The number of subjects showing each of the symptoms 6 months after injury is presented in Table I.

This scattering of symptoms raises the question of the definition of the post-traumatic syndrome. We considered the definition of Raines *et al.* (3, 16), based on their study of Marines who had suffered head injuries during the Korean conflict. Their definition appears quite reasonable: the post-traumatic syndrome consists of headache as a prominent symptom associated with at least one each of the "intellectual" symptoms (impairment of memory or concentration) and emotional symptoms (anxiety or irritability). However, among our subjects this definition excluded quite a few who had significant symptoms but did not meet the above criteria.

The issue is complicated by the fact that

each symptom can be caused by organic brain damage or by emotional factors. Furthermore, there is considerable overlap with the symptoms of the traumatic neurosis, as commonly understood (or, post-traumatic hysteria, in the usage of Brosin (2) and others.) Some of our subjects, if examined by a psychiatrist, would be diagnosed traumatic neurosis or post-traumatic hysteria, while a neurosurgeon might classify the same patients as post-traumatic syndrome.

Therefore, it was decided to ignore temporarily all possible classifications, and instead study all the symptoms of all the patients. The reasoning was that most patients had had one or more of the symptoms listed above at some stage of their convalescence. They had suffered to a greater or lesser degree, and the symptoms had persisted for varying periods. There was a continuum extending from the least degree of symptoms and incapacity to the highest. Each patient was rated on a scale from 1 to 5 by the psychiatrist who interviewed him. The factors which went into the rating were the degree and duration of symptomatology and incapacity from the symptoms listed in Table I. Regardless of how many of these symptoms the patient had, or what caused them, he received one rating which roughly expressed the degree of suffering and incapacity he had experienced from post-traumatic symptoms. Note that symptoms due to gross neurologic changes are not included here. A rating of 1 is given for the lowest degree and 5 for

TABLE 1
INCIDENCE OF SYMPTOMS 6 MONTHS AFTER HEAD INJURY N=50

Symptoms	Number of Subjects	Percentage of Subjects
Anxiety	26	52%
Headache	26	52%
Irritability	20	40%
Dizziness	18	36%
Fatigability	18	36%
Impaired concentration	14	28%
Impaired memory	11	22%
Insomnia	10	20%
Reduced alcohol tolerance	6	12%
Other Symptoms	7	14%
No symptoms 3 months after injury	11	22%
No symptoms 6 months after injury	13	26%

the highest degree of symptoms and incapacity. Reference will be made below to "severity of post-traumatic symptoms." By that we mean the rating on this scale.

A few examples will help explain this system of classification :

Class 1.—A 25-year-old woman, while walking slipped and hit her head, and was unconscious for a few minutes. She was hospitalized for 4 days, and discharged with the diagnosis of concussion. She was able to return to work within a few days. She experienced some tiredness for about a month, which resulted in her getting a little more sleep than usual. Afterwards she felt fine, with no residual symptoms.

Class 3.—A 30-year-old man who suffered a concussion in an auto accident, was hospitalized for 4 days and returned to work after 3 weeks. Nine months later he still complained of headaches and dizziness which seemed to be worse in strong sunlight. He was able to work but was worried about these symptoms, felt there must be definite brain damage, and feared that he would get worse. His concern over his health was restricting his social life, and he was rather preoccupied with a lawsuit in which he hoped to secure compensation for his injuries.

Class 5.—A 21-year-old man who had a severe head injury in an auto accident, was unconscious for 4 days, and afterwards had aphasia and right hemi-paresis, both of which gradually improved. Six months later he still had difficulty speaking and felt weak. He had all the post-traumatic symptoms except insomnia, and was unable to work. Whereas he previously had been somewhat irresponsible and carefree, he now was serious and cautious.

The distribution of subjects on this symptomatology-incapacity scale is shown in Table 2.

Symptomatology- Incapacity Rating	Number of Subjects
1	12
2	9
3	17
4	9
5	3
Total	50

It will be noted from this table that a sizable number of patients recover promptly (class 1), but that a somewhat larger number suffer moderately severe symptoms for an appreciable length of time (class 3) and that a smaller number have severe symptoms and incapacity (class 5). Classes 2 and 4 occupy intermediate positions.

The rest of the project consisted of a search for those factors which are responsible for severity of post-traumatic symptoms.

The patients were rated in many categories of presumed or possible significance for the post-traumatic syndrome. The ratings were recorded in a manner suitable for IBM tabulation. Many of the variables could be roughly quantified; an example is the symptomatology-incapacity index mentioned above. All the data were then tabulated by use of the IBM 650 digital computer machine. The next step was the search for significant relationships between the severity of post-traumatic symptoms and, on the other hand, each of the other variables. The chi square test of relationship was used. All the chi square values were calculated by means of the digital computer machine.

RESULTS

Some of the more important variables will be mentioned individually. For some of these, the distribution of patients with respect to that variable will be shown; and the presence or absence of relationship with severity of post-traumatic symptoms will be indicated.

1. *Severity of injury.* In evaluating the severity of injury we adopted the standard used by Raines, *et al.* (3, 16) for closed head injuries. There are 3 categories: 1. A blow to the head without apparent neurological significance; 2. Concussion, with no subsequent evidence of brain damage; 3. Prolonged unconsciousness or other evidence of brain damage. The distribution of cases according to severity of injury is shown in Table 3.

No significant relationship was found between severity of injury and severity of post-traumatic symptoms ($X^2=1.6804$; $p>.2$).

TABLE 3

DISTRIBUTION OF SUBJECTS ACCORDING TO SEVERITY OF INJURY

Injury Category	Number of Subjects
1 (least severe)	11
2	20
3 (most severe)	19
Total	50

2. *Degree of pre-traumatic personality disturbance.* Each patient was rated on a 4 point scale as to degree of personality disturbance prior to injury. For the purpose of this study we did not consider the type of personality disturbance, but only estimated the degree of departure from normal. The distribution of subjects according to pre-traumatic personality disturbance is shown in Table 4.

TABLE 4

DISTRIBUTION OF SUBJECTS ACCORDING TO PRE-TRAUMATIC PERSONALITY DISTURBANCE

Rating of Personality Disturbance	Number of Subjects
1 (least disturbed)	13
2	22
3	10
4 (most disturbed)	5
Total	50

Pre-traumatic personality disturbance was significantly related to severity of post-traumatic symptoms ($X^2=26.178$; $p<.01$).

3. *An injury which is psychologically traumatic.*

Example: A 35-year-old man who was driving an automobile was involved in a collision with another car. His brother, with whom he was very close, was killed. The subject is an unaggressive man with a strong conscience. For about 6 months he was preoccupied with thoughts of his brother, and he seemed to blame himself for the accident. He developed marked post-traumatic symptoms with no evidence of brain injury.

Each subject was rated in this category on a 4 point scale, analogous to the ratings previously described. The distribution is shown in Table 5.

TABLE 5

DISTRIBUTION OF SUBJECTS ACCORDING TO DEGREE OF PSYCHOLOGICAL TRAUMA

Ratings of Psychological Trauma	Number of Subjects
1	11
2	22
3	12
4	5
Total	50

Psychological trauma was significantly related to severity of post-traumatic symptoms ($X^2=29.4853$; $p<.01$).

4. *Persistent neurologic defects.* This refers to those defects existing at least 6 months after injury. These were found in 13 patients (Table 6).

TABLE 6

PERSISTENT NEUROLOGIC DEFECTS

Symptoms	Number of Patients
Partial aphasia	3
Post-traumatic seizures	2
Ataxia	1
Other incoordination	4
Loss of smell and taste	3
Impaired hearing	1
Tinnitus	1
Impaired motor power	2
Hyperesthesia of scalp	1

Severity of neurologic sequelae was rated on a 4 point scale. A significant relationship with severity of post-traumatic symptoms was found ($X^2=17.6011$; $p<.01$).

5. *Compensation.* Some form of compensation was involved in 24 cases. There was a significant relationship between the factor of compensation and severity of post-traumatic symptoms ($X^2=9.3599$; $p<.01$).

6. *Special stress in early life.* This includes such factors as open conflict in the family; separation from a parent; and economic or socio-cultural stress of the family in the community. Among those patients (46) who could be rated on this point, 24 had undergone such stress in childhood, and they were found to have worse post-traumatic symptoms ($X^2=66.605$; $p<.01$). Perhaps this factor is related to pre-traumatic personality disturbance.

7. *Psycho-social stress during convales-*

TABLE 7

SEVERITY OF POST-TRAUMATIC SYMPTOMS AS RELATED TO OTHER FACTORS

<i>Significant Relationship</i>	<i>Probable Relationship</i>	<i>No Relationship</i>
Pre-traumatic personality disturbance	Psycho-social stress during convalescence	Severity of injury
Persistent neurologic defects	Duration of post-traumatic amnesia	Sex
Psychologically disturbing injury		Age
Compensation involved		Race
Special stress in early life		Occupation
		Education
		Type of injury (assault, auto accident, etc.)
		History of athletic activity
		Previous head injury

cence. Examples of this are: an unsympathetic environment; the development of a new, painful situation not associated with the injury; or the continuation of environmental stress which existed at the time of injury. There were 22 such patients. They are rated as to severity of stress on a 3 point scale. *There appears to be some relationship between this factor and the severity of post-traumatic symptoms ($X^2=9.6311$; $p<.05$).*

8. *Duration of post-traumatic amnesia* was found to be possibly related to severity of post-traumatic symptoms ($X^2=7.904$; $p<.10$).

Other variables were tested, and no relationship was found between them and severity of post-traumatic symptoms. These are shown in Table 7 which is a summary of the findings.

DISCUSSION

In a personal sense, the most surprising finding was that severity of injury was not related to severity of post-traumatic symptoms. One's clinical impression is that there is such a relationship. Careful re-examination of the data indicated the following possible explanations: 1. This clinical impression is actually based on those patients with residual neurologic defects. These subjects had severe injuries and had more post-traumatic symptoms, but there were many others with equally severe injuries *according to our standards* who made good recoveries. 2. The second point follows from

this, and concerns the manner of rating severity of injury. This was done on the basis of length of unconsciousness and other signs of brain damage at the time of injury. But it is known that some of this damage is reversible; the good recovery of some severely injured patients must be based on this fact. On the other hand, irreversible damage, as detected by persistent neurologic signs, is associated with increased post-traumatic symptoms. 3. A third reason for the lack of relationship is that many patients had relatively severe reactions to minor injuries.

Turning to the psycho-social factors, one of the most definite relationships is between pre-traumatic personality disturbance and post-traumatic symptoms. In considering this result, it should be remembered that our estimate of the pre-traumatic personality is of necessity approximate. Rating was based on our clinical impression during the interviews and a review of the patient's social, occupational and family adjustment prior to the injury. Essentially the same method has been used in other studies (5, 8, 16).

In spite of this caution, we believe there is a causal relationship between pre-traumatic personality disturbance and post-traumatic symptoms. It seems that where a personality disturbance exists, a head injury is usually enough to upset the emotional balance and result in prolonged symptoms. We found this to be equally true for neurotics and patients with character disorders.

Some of the patients showed neurotic reactions in addition to, or in place of, post-traumatic symptoms. The most common ones were the tendency to use the injury as a face saving device for all other difficulties; the fear that a vital part of the body was irreparably injured; the feeling of vulnerability, or that one has been abandoned by fate; guilt reactions if the subject contributed to the accident; and fear of insanity.

Interestingly, some patients with personality disturbances recovered promptly, and showed no tendency to use the injury or their symptoms in the service of neurotic needs. Evidently, for these subjects the injury was not particularly stressful psychologically; perhaps it did not touch upon their important conflicts. Also, it seems that these patients had no previous tendencies to somatize their anxiety.

Injuries which were psychologically traumatic seemed closely related to severity of post-traumatic symptoms. However, we regard this result as merely suggestive because of the difficulty in retrospectively rating how disturbing an injury was. Both patient and examiner are apt to be influenced by the severity of present post-traumatic symptoms, which of course vitiates any subsequent correlation between the two factors. Our clinical impression is that the emotional impact of the injury is indeed important.

In those cases where compensation was involved, the patients had relatively worse post-traumatic symptoms. Whether the matter of compensation was settled or not did not appear significant. We have no explanation for this latter fact.

IMPLICATIONS

These results are generally in line with those of other authors (5, 8, 16, 21, 23) in indicating that emotional factors and circumstances of injury seem to be relatively more important than severity of injury (as ordinarily measured) in causing post-traumatic symptoms. Yet, organic, structural changes are also important, as indicated by the significance of neurologic sequelae.

At this point it should be stated that in spite of our emphasis on organic versus psychogenic, we share the present day

holistic view of man. By "organic" we refer to those biological processes which at present are studied by a certain type of operations (neurologic exam, EEG, etc.); and by "psychogenic" we mean processes which are studied by other operations (psychiatric interview, etc.). We believe that in the present state of our knowledge the distinction is valid and necessary.

One reason for the distinction is that it determines the physician's therapeutic approach. Lynn, *et al.* (9) have pointed out that where the organic factors predominate, the doctor aims for retraining the patient and development of his undamaged capacities. He is oriented towards the probable acceptance of a certain amount of limitation of function. On the other hand, in psychogenic problems the indicated treatment is some form of psychotherapy, with the assumption that full recovery is possible. The proper balance of these two approaches depends on the accurate appraisal of the relative importance of each factor.

The problem of determining the extent of residual brain damage in individual cases can be extremely difficult. Various authors (2, 21) have drawn up lists of criteria to distinguish organic from personality determinants, but they conclude that frequently the distinction is still hard to make. Often some of the criteria point towards an organic origin and others toward an emotional one. The electroencephalogram may be of help, but can not be relied on confidently because of false positives as well as false negatives (2).

Obviously, the situation will be improved only by the development of better neurologic and psychiatric diagnosis. In each case, advances may take the form of entirely new diagnostic modalities or better application of existing ones. For example, on the neurologic side, the use of the electroencephalogram may be refined so that its value is increased.

Regarding the psychiatric aspects, at Temple University Medical Center a program of psychiatric follow-up of head injured patients has been instituted, in close conjunction with the neurosurgical follow-up. The hope is that continued contact with these patients will reveal more exactly how neurotic forces operate to prolong symptoms

and disability; and how these forces interact with symptoms of organic origin.

The second purpose of our follow-up is therapeutic: we attempt to deal with the neurotic and regressive reactions which occur. In most cases supportive therapy suffices. Where the injury has released a deeper neurosis, it is handled in the usual psychotherapeutic ways. Attention is also directed to the patients' reality situations: they are helped to obtain needed services from outside agencies such as the State Bureau of Vocational Rehabilitation and sheltered workshops. The results of this program will be reported in the future.

SUMMARY

In this study the post-traumatic syndrome was investigated. It was found difficult to define the limits of this condition, and particularly to distinguish it from post-traumatic hysteria. Therefore, both diagnoses were temporarily ignored, and the injury was broadened to the general sequelae of head injuries, other than definite defects caused by known neurologic lesions.

These sequelae are psychosomatic in the truest sense of the term. They represent an intricate combination of organic and emotional processes. It seems that the symptoms following head injuries signify the sum of two quantities: 1. The damage to the brain and its surrounding structures; and 2. The patient's emotional reaction to this damage and to the experience of the trauma.

The important problem is to assess the proportion of each quantity in individual cases. In the hope of contributing to its solution, psychiatric follow-up of head injured patients has been instituted.

PRINCIPLES OF ADMINISTRATIVE THERAPY

D. H. CLARK, F.R.C.P.E., D.P.M.¹

In a previous article(2) the author described Administrative Therapy—the art of treating patients in a psychiatric institution by administrative action. Some of the pains and problems of the administrative therapist were described and some of the methods to be followed in organization of the patients' life, in staff and medical organization and in leadership of the therapeutic community. This paper attempts to explore further aspects of administrative therapy.

An increasing number of experiments, all claimed as "therapeutic communities" are being set up in Britain and the U.S.A. Though these projects cater to differing groups of patients and consequently have different organization, they have in common a belief that modifying the social structure will bring about desirable changes in the patients. This is no new idea; as T. P. Rees has pointed out, this was the belief that inspired most of the great founders of institutional psychiatry and was expressed in their term "moral treatment." In their time, however, they argued from self evident principles arising from religious belief or the doctrines of the Age of Reason, though as pragmatic physicians they justified their theories by their successes. Now we base our theorizing on the work of social scientists, in particular the descriptive studies of social anthropologists studying mental hospitals and comparing them with other societies, the experiments of social psychologists with experimental groups and the experiences of psychiatrists in group psychotherapy. We like to believe that we base our practice on a more secure theoretical foundation than our forefathers; let us hope so, lest our endeavours decline into dreary custodialism as did theirs.

Most of the studies describe the changes made in the organization: the increased consultation, the opening up of communication, the democratic practices. They usually give hints of the anxieties aroused and the storms endured, and a few discuss the

method used to introduce the changes. Hardly any of the studies have discussed the actions of the leader of the therapeutic community. There is even a sort of pretense that he hardly exists—that it could all have happened without his presence. Much of the exploration and innovation in the experiments is, of course, done by the junior staff and the patients themselves and it is from them that the enthusiasm and therapeutic drive comes; the leader is but a catalyst. Yet it is as fatuous to ignore his contribution as it is to overestimate it. The papers describing therapeutic community experiments are nearly all written by the initiators themselves, an impressive group of men and women whose personal contributions must have often been decisive.

It is important to examine the methods of administrative therapy for others are seeking to repeat the work. Young psychiatrists are trying to set up therapeutic communities and are puzzled when things go wrong. It is worth remembering that the first recorded attempt at a Therapeutic Community was a failure. Bion and Rickman aroused such hostility by their attempts to restructure Northfields Hospital that they were extruded, as Taylor(7) describes.

The introduction and maintenance of a therapeutic community is not a simple task which can easily be accomplished by naïve enthusiasm. The old custodial regime has persisted because it offered comfort and relief for anxiety for many of the staff, especially those in senior positions, and attempts to rock it may be defeated by hostility and inertia.

Administrative Therapy is the art of organizing and directing a human organization in which psychologically disturbed people may acquire great personal stability and better social adjustment. It may be practiced in a single ward, in a section of a hospital or in a whole hospital. It is a form of large-group therapy in which most of the work is done with the staff so that the patients may benefit from the atmosphere and environment produced. It draws most of its ideas, concepts and methods

¹ Medical Superintendent, Fulbourn Hospital, Cambridge, England, Associate Lecturer in Psychiatry, University of Cambridge

from individual psychotherapy and the psychiatrist's understanding of human dynamics but owing to the size of the groups concerned there are other areas of knowledge which are relevant, in particular, social psychology, social anthropology and the methods of business administration.

An administrative therapist comes to a custodial mental hospital and wishes to lead it to a more therapeutic way of functioning; he knows that the job can be done better and the patients helped more effectively, but the staff of the hospital, the patients and the neighbouring community do not know it. How is he to help them make this change? Much depends on how the staff feel about their work; if they are secure, confident, settled and certain that they are doing things well and that there is no ground for criticism, his task will be difficult indeed. Nowadays, however, a mental hospital running on custodial lines is not usually settled and confident. Morale in such institutions tends to be low, and there is a great deal of doubt, self questioning and anxiety among the staff, a whisper of new things afoot elsewhere, a query whether they could perhaps not learn something, coupled with sturdy denials that there is anything to be said for any of these new fangled notions.

First, the administrative therapist must assess the situation fully; assess the hospital, its morale, its functioning, the key persons and their knowledge, skills and attitudes, and most important the potentialities of the situation: the desire for change, the possibilities of change, the chances of money for new buildings, new developments and extra staff. After he has made this assessment he can begin to plan the approach; the change should be gradual and the innovator should go slowly. As occasion offers, the therapist must enunciate the principles that he regards of value in the hospital. These were clearly set out in the W.H.O. Report on the Community Mental Hospital(8): the need to trust the patients, to give them freedom, responsibility and a fruitful and active life. Though in that report they are mentioned as principles to be applied to the patients, they also apply to the staff. They too must be shown trust; they must be given scope for

initiative; they must be allowed as much responsibility as their training, knowledge or personality structure will permit and they must have a full, active life. Many of the vicious degenerate practices of the old mental hospitals arose in the sheer boredom of staff penned for long years in a custodial hierarchy waiting to step into dead men's shoes.

Who are the people to help in the process of change? The social anthropologists have something to teach us here; they tell us that the first person to greet the newcomer to any community is a deviant. The administrative therapist should not immediately work with the first person who comes to him with ready protest. Further he should not bring in from outside too many new people who "know his ways." If he does there is a sad danger that they will be treated as other bright doctors, administrative nurses, occupational therapists and others have been in the past; they will be quietly ignored, cold shouldered and finally so discouraged that they leave, saying that the organization has beaten them. The Cummings(3) have pointed out that however bad a hospital may be, it is an ongoing organization and its stability depends on the norm bearers, the culture carriers. Belknap(1) pointed out in his study that the senior attendants were in fact the people who kept the hospital going and who maintained its traditions, and that attempts to impose reform on them by force had always failed. If, however, the norm bearers change their way, the new traditions are truly embedded in the fabric of the hospital. The Cummings suggested, that a suitable procedure is to find the accepted and respected leaders of the culture-carrying group and bring them to see the value of change. The Cummings went about this by inviting the staff to elect the new assistant chief male nurses and then worked with them. It is often possible to arrange for the culture carriers—the charge nurses, ward sisters or senior attendants most respected by their peers,—to go away on refresher courses or to spend a few weeks working in a hospital of more advanced methods. When they come back they can be given a free hand to show some of the things they have learned. (Nothing is of course more damag-

ing than to send a person on a course and then put him back into the same old stultified set-up.)

The new administrative therapist should examine most closely the communication system of the organization. This will nearly always be found to be stultified and hierarchical with a great blockage of information. Instructions are distorted as they filter downward, and only highly selected (and often misleading) information is allowed to reach the top. This can be changed. The most effective way is to start new meetings; this will gradually lead to group government and decision making. The administrative therapist finds group government congenial; it is a most effective way of allowing the development of new ideas. In the administration of the hospital there should be groups of senior medical and nursing personnel and groups of senior hospital officers. In the ward, group meetings, both of all the patients and of the staff are essential. In these meetings people who have never previously had a chance to make a contribution are delighted with the opportunity to come forward and speak of the things that they know; the value of this information flowing upward is immense. At the same time they see policy being formed and partake in working out its details, so that they too are committed to the new processes and changes that develop. These groups too are occasions to enunciate the principles of therapeutic organization and to work it out in practical detail.

Sensitivity in administrative action is essential too. Every administrative action can profitably be considered as carefully, and weighed as thoroughly, as the interpretation in psychoanalysis. It is not only what you say, but when, and how you say it that matters. An unpalatable decision, if delivered in the atmosphere of a friendly interview, may be accepted when it would be grossly humiliating and disruptive if communicated in a curt written message or in an open meeting. Of any administrative action it is pertinent to ask: How was it done? Did it have the desired effect? What other effects did it have? and finally, What good did it do to the patients and the staff?

Crises occur in every organization and are

not in themselves to be deplored. If everything runs smoothly, and no crises occur, it is likely that the community is ceasing to be therapeutic. It is the manner in which the crises are worked out, the open discussion, the acceptance of the solution put forward by the group rather than the resolution by panic-stricken authoritarian ukase that is therapeutic and bears within it the hope of further growth.

The administrative therapist must pay attention to the sanction and reward system of the organization. This is very important. In the classic custodial institution, promotion was by seniority and only reprimands could debar an attendant; the way to get on was to behave with extreme caution, never show any initiative lest you be reprimanded, and wait so that in due course the post of charge attendant fell to you. Punishment too often concentrated on entirely negative aspects of the functioning of the hospital: dire punishment for coming in late, for losing keys, for being involved in the disappearance of a pair of patient's boots. The end result was the traditional cautious, repressive, sullen attendant. This must be changed. Promotion should, of course, be by merit (as it already is in many hospitals) but it should not be by merit in examinations alone but by merit in patient management. Those nurses who develop therapeutic groups among patients or who take the lead in new experiments should find that this leads to promotion, whereas those who hang back from such innovations find themselves unsuccessful. There are also negative sanctions. Punishment is alas necessary in human organizations; the staff will watch with great care to see what things the new administrative therapist regards as bad. Any reprimand should be related to the therapeutic goals of the community.

The therapist must fulfil the functions of spokesman and leader of the therapeutic community. He should set goals and coin slogans; he must speak up for the community when their policies come under criticism; he must speak to the powers in the land—the Ministry of Health or the Commissioner for Mental Hygiene; he must also explain their work to the local community. He must ward off the attacks of

those who wish to limit or damage the freedom of the therapeutic community after such unavoidable happenings as accidents, deaths, drunken brawls or illegitimate babies, and he must plead for the money needed for staff, new buildings and other developments. He must judge when to pass on to the group the anxiety that these pressures engender and when to contain it within himself.

An important sphere of work is the barrier between the hospital and the community. Goffman(4) has pointed out that the traditional mental hospital is a total institution shut off from the outside world and living its own strange bizarre life with not only a wall round it but a real psychological barrier against staff going out and visitors, Press and others coming in. All that can be done to break this down is to the good. Staff living out of hospital and taking an active part in the life of the community, visitors coming into the wards of the hospital, patients going out to work in surrounding factories, voluntary workers coming in and taking part in the clubs and socials of the wards are all moves that tend to equate the standards of the outside world and those of the hospital community.

Administrative therapy in an established therapeutic community shows certain differences. All the above principles apply but much of the ground work will already have been done. The administrative therapist will be doing his work in groups, pulling together colleagues of all levels who are anxious to contribute and to make a place where patients can progress and recover. Many decisions will be made by the groups, and the therapist will be the instrument to carry them out. His main task will be to maintain the therapeutic atmosphere, to see that the community does not become diverted towards other aims or its enthusiasm dissipated. One medical superintendent once said "Do something new every three months! It doesn't matter what you do, but do something new and keep them thinking!" The method was authoritarian, but the idea valuable; there should always be new moves and developments afoot within the community so that it does not sink, as any group working with long stay disorders may, into dull dreariness. It is not necessary

for the administrative therapist himself to have bright ideas. In the open communications of the therapeutic community new ideas are forever coming up. The administrative therapist's task is not to be a creator but a selector, seeing which projects are to be encouraged and given scope and which deferred; he acts like a telephone operator, selecting those communications which are of immediate value and passing them through, choosing which are to wait for a time and which should be ignored.

The administrative therapist has a constant scanning duty to perform; he must maintain some form of contact with all levels and sections of the therapeutic community and feel and know what is going on in all groups, even those with which he has no direct communication. It is said that the best manure is the foot of the farmer and in the same way administrative therapists should constantly be moving through the unit listening to all and knowing how things are going. Parkinson(5) under the name "injelititis" has described brilliantly the condition of sagging morale in a department. The administrative therapist must forever be on the look out for incipient injelitis in parts of his organization. When he finds it (as he will) he must at once try to assess what is happening and why things are going amiss. If there are grievances he can attempt to put them right; an organization in a state of demoralisation is, however, always full of grievances and often the best thing is not to attempt to put right the grievances that are alleged but seek immediately a new goal to which the dissipated can turn their energies. At other times an attack on the organization can be therapeutic. Sivadon(6) believes that an attack on a public grievance can be a valuable rallying point to arouse constructive enthusiasm and says that he is glad that there is "always something wrong" in a hospital.

Valuable therapeutic developments often come from groups of patients and staff who are moved to attempt some group activity. The administrative machine may attempt to crush these, especially if they appear to be an attack on the existing order. It is a most important function of the administrative therapist to check the machine or the

frightened wrath of the criticised administrator, and to act as an umbrella over the tender developing plants of group activity so that they may take root and flourish. In particular he must ward off the attempts of the tidy-minded administrators, auditors and others who are only too ready to swathe any new development in red tape until it wilts and dies.

There are certain built-in tensions to which the administrative therapist must give constant attention. He must constantly bring professional groups together and try to get them to cooperate, but if he is wise he will recognise that there are certain tensions that can only be accepted and minimized; for example, the tensions between the full-time trained nurses and the part-time untrained nursing assistants, the tension between occupational therapists and women nurses attempting to activate the same group of patients, the tension between male nursing staff and garden staff and the general tensions between clerical and therapeutic staff. It is better to accept these than to pretend they do not exist and at certain times such as the Annual Sports, they can be used to stimulate rivalry and to enliven the proceedings.

SUMMARY

Further aspects of Administrative Ther-

apy are explored. Some of the methods to be used in transforming a custodial into a therapeutic institution are discussed and also methods of maintaining the momentum of an established therapeutic community.

BEHAVIORAL CHANGES DURING HYPOTHALAMIC OR LIMBIC STIMULATION IN THE MONKEY^{1, 2}

LORNE D. PROCTOR, M.D., ROBERT D. KNIGHTON, M.D.,
JEROME LUKASZEWSKI, M.A., AND JOSE BEBIN, M.D.³

This presentation is a sequel to one given in April, 1958(1), in which the reticular formation primarily was the site of stimulation. Such stimulation produced changes in consciousness, genital responses, hemiballismus, rage responses and finally yawning. In the present report we have extended our observations of behavioral and depth EEG changes related to stimulation by electrodes in the reticular formation, the hypothalamus and limbic system.

TECHNIQUE

Our present electrodes are a modification of the Jasper-Delgado type, consisting of 4 strands of #50 platinum-tungsten Teflon covered wire. The tips are placed approximately 2.5 mms. apart in the vertical plane, bared for 0.5 mms. and the most distal tip bent into a hook. The assembly of 4 wires is enclosed in a polyethylene tube of just sufficient diameter to prevent the wires moving in vertical relationship to one another, and the bared ends (and the distal hook) arranged to protrude through the polyethylene tubing. The electrode placement is made using a Universal Stereotaxic instrument (Baltimore), and a #22 gauge lumbar puncture needle-shaft acts as the electrode carrier. The hook engages in the opening at the tip of the lumbar puncture needle-shaft, which shaft is held in the chuck of the stereotaxic instrument's carrier. On reaching the desired placement in the brain, merely withdrawing the lumbar puncture needle allows the electrode to remain "hooked" into the point of placement in the brain(2). This provides 3 sets of bipolar electrodes in the vertical plane for each multipolar electrode placement. The

poles of the electrodes were designated A, B, C, and D; A designating the pole at the tip of the electrode.

The electrode leads are firmly fixed as they pass through the skull, by a nylon clip screwed into the skull, and are carried under the scalp to a nylon connector plug attached to the posterior portion of the monkey's skull. This technique has provided a satisfactory means, during the past 6 years, of obtaining depth recordings and for stimulating the various areas of the reticular and limbic systems. Resting depth EEG recordings are now consistent from any selected area in these systems over periods of as long as one month. A method has been devised so that we can now record 3-7 mms. distance from the site of stimulation in the reticular or limbic systems without stimulus artefact or significant blocking(3).

The parameters of stimulation which produce behavioral changes with a minimal chance for concomitant "Jacksonian-like" motor responses has been determined in our previous investigations(1). With this in mind a Grass S4B stimulator was used to supply monophasic square top impulses, with a duration of single impulse 0.20 msec., a delay between impulse trains 0.015 msec., and only the voltage, frequency and polarity of the stimulus varied.

The monkey is seated in a chair with a "corset" restraining him from hips to lower ribs in front, and his hands are limited by cords attached by soft metal cuffs above the wrists or by a plastic collar about the neck. He thus is able to perform manual movements for psychometric testing, etc., but cannot reach above his head to pull at the electrode connections to the EEG unit or the stimulator.

The EEG is analysed as to frequencies by an Offner frequency analyser, which analyses in 10 second intervals the output of any one channel of an Offner transistor EEG unit.

The behavioral changes are recorded by

¹ Read at the 116th annual meeting of the American Psychiatric Association, Atlantic City, N. J., May 9-13, 1960.

² This investigation was supported by National Institutes of Health Research Grant M-2474.

³ From the Department of Neurology and Psychiatry and the Division of Neurosurgery, Henry Ford Hospital, Detroit, Mich.

both still photographs and 16 mm. colored movies.

The monkey is tested psychometrically, using the oddity test(2), for any change in ability to perform a learned procedure as a result of stimulation.

We have been able to make 4-5 separate multiple electrode placements in a number of our animals. These electrodes remain in place over a period of 2-4 months, at the end of which time the animal is sacrificed and the brain perfused with 10% formalin. After 2-3 weeks fixation the brain is sectioned and examined macroscopically and microscopically for confirmation of electrode placements. In many cases only the odd round cell constitutes the tissue reaction along the path of the electrode and at the electrode sites.

Stimulation of electrodes placed outside of the reticular and limbic systems have allowed control observations in our investigation.

In the interest of space only 2 sample protocols on stimulating in the hypothalamic and limbic areas are reported (of the 6 protocols recorded).

OBSERVATIONS

Hypothalamic Stimulation

Monkey #19.—Electrode location: (pole D not connected). Pole A was situated in the left lateral wall of the third ventricle, and pole B was 2.5 mm. above in the left dorso-medial nucleus of the thalamus.

Stimulation between A & B at 400 cps, polarity #1, and 8 volts resulted in bilateral pupillary dilatation, the left pupil recovering during stimulation, frequent guttural cries and the arrest phenomena.⁴ The animal made no correct choices (0/6) on the oddity test during stimulation as compared with 4/6 prestimulation. The quivering (anxious) mouth response appeared throughout the period of stimulation. Reversing the polarity merely reduced the degree of response.

Electrode location: Pole A was situated in the left lateral wall of the hypothalamus, and pole C in the left nucleus ventralis anterior of

the thalamus (pole B in the left dorso-medial nucleus of the thalamus).

Stimulating between A & C or between B & C at 400 cps, polarity #1 and 6 volts produced the same response described on stimulating between A & B except it was milder in degree.

It is noteworthy that 30-60 minutes after the final stimulation in the above hypothalamic areas (Monkey #19), when the animal was back in his home cage, he appeared confused, uncomfortable and frequently lay down, cried and would not take food. This reaction disappeared later in the day.

The next day using polarity #2 and increasing the voltage to 15 through 30 volts at 400 cps, between poles A & B, there occurred maintained bilateral pupillary dilatation, and at 32 volts the animal ejaculated, urinated and had a mild right Jacksonian episode. Immediately following this last stimulus, the animal was blind and this impaired vision continued for approximately 5 days. Following recovery of vision, stimulation using 400 cps, polarity #2, and 21 volts between poles A & B was required to produce confusion, no doubt due again to visual impairment and anxiety. The animal showed no arrest phenomena nor anxiety below 21 volts. One month after this latest stimulation, restlessness, anxiety, and the arrest phenomena occurred using only 9 volts between poles A & B. Stimulation between poles A & B, with voltages just below those producing pupillary dilatation, invariably resulted in frequent guttural cries during the stimulation period.

The depth EEG patterns, at rest, in the areas of the hypothalamus examined (Figure 1), showed a predominance of slow wave high amplitude activity (1.5-7 cps). This pattern changed on stimulation of the opposite hypothalamus, showing a reduction in the amplitude of the slow wave activity, but 20-30 seconds post stimulus the EEG pattern returned to the prestimulus pattern. Our small number of observations of this phenomena would not allow us to draw conclusions as to its significance.

Incidentally, between electrodes, poles A & D located in the left anterior hypothalamus, a 35 cps discharge was recorded at rest (Figure 1), and was found to increase in extent (not amplitude) on stimulating the opposite hypothalamus. The onset of these 35 cps bursts occurred at various stages of respiration, and were thought to

⁴ Arrest phenomena indicate a behavior characterized by impaired awareness. The animal may only show this defect by its inability to perform a learned task correctly, or the impairment may be so severe a trance-like state exists so that the animal shows no reaction to its environment.

be discharges via the anterior hypothalamic pathways of the olfactory tract.

Limbic System Stimulation

Monkey #18.—Electrode location : (poles C & D not connected). Pole A was situated in

the anterior tip of the right temporal lobe (hippocampal gyrus), and Pole B was 2 mm. above in the right uncus (periamygdaloid area).

Stimulation between A & B using 400 cps, polarity #1 and 4 volts resulted in the animal becoming restless, but slept seconds post stimu-

FIGURE 3
EEG FREQUENCY SPECTRA FROM SAME AREA IN HYPOTHALAMUS
RECORDED 33 DAYS APART.

lus. At 6 volts the animal appeared to become drowsy and slept post stimulus. At 10 volts, with the commencement of stimulus, lip movements occurred but ceased during stimulus, and the animal slept post stimulus. Using 30 cps, polarity #1 and 2-40 volts, no behavioral changes were noted.

Electrode location: Pole A was situated in the left hippocampal gyrus (upper portion), and pole B was 2 mm. above in the uncus.

Stimulation between poles A & B using 400 cps, polarity #1, and 2-20 volts produced no behavioral changes; changing to 30 cps, some eye blinking occurred at 15 volts.

Electrode location: Pole C was situated in the amygdala, and pole D was 2 mm. above still in the amygdala.

Stimulation between poles C & D using 400 cps, polarity #1 and 6 volts produced gritting of the teeth; at 10 volts both pupils dilated, and at 15 volts both eyes blinked. Changing to 30 cps, at 12 volts, blinking occurred and at 15 volts blinking of the eyes and chewing movements were noted.

In Figure 2 the depth EEG pattern at rest, from the left amygdala, suggests a broader

frequency spectrum for the predominant frequencies (1.5-11 cps) that seen in the depth EEG from the hypothalamus (Figure 1). Incidentally, stimulation in the left parieto-occipital white matter increased the amplitude of the slow wave activity in the amygdala.

SUMMARY

On stimulating in the hypothalamus, the following responses were observed: (a) pupillary changes, (b) anxiety, panic and agitation, (c) guttural cries, (d) arrest phenomena, (e) somnolence, (f) gritting of teeth, chewing, etc., (g) ejaculation and urination, (h) Jacksonian-like motor episodes, (i) head turning and (j) loss of vision.

On stimulating in the limbic system, the following responses were observed: (a) alerting, (b) trismus, (c) gritting of teeth, (d) smacking, licking and chewing, (e) guttural cries, (f) pupillary changes, (g) eye blinking, (h) Jacksonian-like motor episodes and (i) lethargy, post stimulus.

FIGURE 4
EEG FREQUENCY SPECTRA FROM SAME AREA IN AMYGDALA
RECORDED 29 DAYS APART.

On stimulating in the mesencephalic reticular formation, the following responses were observed: (a) spastic chewing movements and inability to swallow food, (b) gritting of teeth, (c) confusion—even to the point of trance-like states.

On stimulating in the basal nuclei, the following responses were observed: (a) loss of conjugate deviation of eyes and (b) head turning.

On stimulating in the parieto-occipital white matter, the following responses were observed: (a) pupillary changes, (b) marked conjugate deviation of eyes with head and body turning, (c) bilateral nystagmus, (d) tremor and (e) post stimulus, chewing movements and hippus occurred.

The study of the EEG patterns at rest or following stimulation in the limbic, hypothalamic and mesencephalic areas pointed

up the problem of EEG evaluation, and after much thought and consultation we concluded the use of frequency analysis offered the most practical means of comparing our EEG findings.

The use of a frequency analyser allows description of the EEG record in two dimensions only; the frequency and the amplitude of the signals at a given frequency. The frequencies are fixed by the design of the analyser, and are noted in Figures 1 and 2. The EEG activity is analysed for a finite period of time (10 seconds) and this information is stored, by means of capacitors, that are later discharged so that a graphic record is obtained of the total amount of activity—in terms of amplitude—at each of the frequencies analysed during this 10 second period. It can be seen that certain compo-

FIGURE 5
COMPARISON OF EEG FREQUENCY SPECTRA RECORDED FROM
MIDBRAIN RETICULAR FORMATION AND FROM AMYGDALA.

nents of the total signal are lost by this analytical method; namely, the phase relationships of the various frequencies, and the time of occurrence of a particular frequency during the 10 second interval. With full appreciation of the limitations of this analysis, we are reporting a preliminary description of our EEG findings.

The electrical activity of the hypothalamus appeared to be stable with regard to the inter-relationships of the various frequencies one with the other. This can be seen in Figure 3 which allows comparison of the amplitude of the activity at the various frequencies. The activity during the initial recording (2/6/59) had a much higher amplitude than did the activity recorded later (3/11/59), however, the pattern of activity remained relatively invari-

ant. Indeed, when the amplitudes of the signals at the given frequencies were correlated, a value of 0.97 was obtained. This value was found to be statistically significant, and indicates that the amplitude shifts between the various frequencies on a given day were stable when compared to the shifts on another day. The confidence limits for the correlation based on a sample of 20 frequencies ($N=20$) are 0.92 to 0.99 with a probability of 95%. These figures indicate the range through which the correlation can be expected to vary on the basis of different samples, and show that the EEG patterns reported here are characteristic of the activity which generally would be found in this area under similar conditions.

Figure 4 indicates the EEG activity found in the amygdala area. It shows that

the activity on two days, approximately one month apart, was almost identical in terms of amplitude and the frequency spectra. The stability of the EEG patterns of the amygdala area (medial amygdala and junction of the amygdala and putamen) is indicated by the correlation of these two frequency spectra. This correlation was 0.94 and was found to be significantly different from zero beyond the 1% level of confidence. The confidence limits for this correlation ($N=21$) are 0.86 and 0.98 with a certainty of 95%. These findings confirm that the activity of the amygdala is relatively stable over this period of time (one month).

Figure 5 allows comparison of the activity of the reticular formation in the vicinity of the red nucleus with the activity in the anterior commissure just dorsal to the amygdala (limbic area). It can be seen readily that the signals, at a given frequency, are generally of greater amplitude in this region of the mesencephalic reticular formation than those emanating in the regions of the anterior commissure. The frequency spectra are also obviously dissimilar.

DISCUSSION

There were no well defined limits established as to the extent of the stimulation fields about the various bipolar electrodes used in this investigation. It will be noted that several of the hypothalamic bipolar electrodes had one pole in the adjacent thalamus, and several of the limbic bipolar electrodes had one pole in the basal nuclei area. One pole of a basal nuclei bipolar electrode was situated in the preoptic-supraoptic region. However, the larger portion of the area between the poles of the above group of bipolar electrodes was in the region under investigation, *i.e.*, hypothalamus, limbic system, or basal nuclei area, and we, therefore, suggest the responses on stimulating by these electrodes were predominantly the responses of the hypothalamus, limbic system or basal nuclei region.

As noted previously(4), the changing of frequency of the stimulating impulse altered significantly the response both in degree and quality, and the characteristics of this alteration depended upon the area stimulated. No consistent response characteristic

was seen to be dependent upon the frequency of the stimulating impulse, but the higher the frequency, the less likely was the stimulus to produce Jacksonian-like motor responses at a given voltage.

In this investigation, the changing of polarity of the stimulus altered predominantly the degree, rather than the quality of the response.

Anxiety was the most common response on stimulating in the hypothalamus, and by merely increasing the voltage of the stimulus the anxiety response in a given area could be altered to panic, and in some areas to agitation suggesting rage. This phenomenon was seen particularly on stimulating in the anterior hypothalamus. This finding is interesting as Hess(5) reports motor restlessness and flight response areas in the cat to be predominantly situated in the posterior hypothalamus (ergotropic centers(6)), and the more homeostatic protective response areas (trophotropic areas (6)) in the anterior hypothalamus. In our investigation we were dealing with a different species (monkey), and our stimulating impulse is of a higher frequency. The question does arise in our minds as to whether the parameters of the stimulating impulse might alter the response from any given area in the hypothalamus, making it possible to obtain a more extensive area from which these various responses (ergotropic and trophotropic) could be elicited.

Our previous observation of anxiety, panic and agitation on stimulating in the mesencephalic reticular formation(4) is in keeping with Hess(5) who reports the flight and motor restlessness responses can be followed on stimulating backwards "into the central gray matter of the mesencephalon."

Somnolence was produced by stimulating the anterior hypothalamus, an area not far distant from Hess's(5) "hypnogenous zone" that he places in the intralaminar nuclei region.

The oral responses included gritting of teeth, chewing movements, smacking of lips and licking. Only the smacking and licking responses were limited to limbic area stimulation, the remainder of the oral responses occurring on stimulation of the posterior hypothalamus, limbic areas or

mesencephalic reticular formation. An interesting variant of the oral responses occurred on stimulation of a limbic area, namely trismus. Another variant occurred on stimulating the mesencephalic reticular formation when, rather than trismus, the animal had difficulty chewing and swallowing food because of spasm of the muscles involved with these functions. The mouth could be opened, but with difficulty in this instance.

The arrest phenomenon progressing to trance-like states was a response common to stimulation of the hypothalamus and mesencephalic reticular formation areas.

The Jacksonian-like motor episodes observed occurred on using relatively high voltage for stimulation.

At this time we have no explanation as to the dynamics for the production of eye blinking during stimulation of the limbic area, nor an explanation for the production of the 5 day period of blindness following "high voltage" (32 volts) stimulation of the lateral portion of the hypothalamus.

We were impressed with the number of similar responses elicited by stimulation in either of two or even any of three of the systems investigated (hypothalamus, limbic areas and mesencephalic reticular formation). It would appear these systems have many ramifications each with the others. Pribram's(7) concept that multi-linked homeostats condition the responses from such areas as the "limbic end brain," and the reticular formation, providing negative and positive feed-back circuits, allows much speculation as to the variety of pathways through which stimuli occurring in either the limbic or reticular systems could be directed. These theoretical circuits could serve to explain the similarity of responses

on stimulating at different areas in the brain.

CONCLUSION

Stimulation of various areas of the limbic and hypothalamic regions in the Macaca mulatta resulted in a variety of responses. These responses were compared with those obtained on stimulating areas of the mid-brain reticular formation.

It would appear that "overlapping" occurs as to the function of the limbic system, the mesencephalic reticular formation and the hypothalamus, in view of the similarity of behavior patterns elicited by stimulating some areas in these three different regions.

The EEG patterns from the limbic, reticular (mesencephalic) and hypothalamic systems varied significantly so as to suggest that each system may function basically as an individual component system of the brain, probably influenced by ramifications one with the other. This EEG study is a preliminary investigation.

THE PSYCHOTHERAPY THAT WAS MORAL TREATMENT¹

ERIC T. CARLSON, M.D.,² AND NORMAN DAIN, M.A.²

INTRODUCTION

With the rise of inductive science in the 17th and 18th centuries, scientists and philosophers inevitably adopted a naturalistic approach to emotional illness as an earthly rather than supernatural sickness. The enlightened men of this hopeful era believed that the dramatic exigencies of the individual's life caused his illness, and that consequently the individual deserved sympathy, respect, and, most of all, assistance in conquering his life-produced situation. When this new attitude towards the disturbed person achieved wide acceptance among intellectuals at the end of the 18th century, modern psychiatry emerged as a medical specialty.

Medicine approached mental illness in the light of contemporary physiology: since it was a disease, it should respond to pharmacological treatment. At the same time, there was a growing understanding that other, nonmedical methods were also useful in treating the mentally ill. The stress laid on these new therapeutic approaches varied widely from writer to writer. Although most physicians employed pharmaceutical therapy, some even felt that all medication was superfluous.

The non-medical methods were known after the 1750's by a variety of terms: "management," "government," "regimen," and, referring specifically to the hospital scene, "internal police." When Philippe Pinel's famous 1801 work, *Medico-philosophical Treatise on Mental Alienation, or Mania*, was translated into English in 1806(1), the phrase "moral treatment" (a literal translation of "*traitement moral*" which persisted

in use into the 20th century) replaced the earlier terms. This shift in nomenclature emphasized that nonmedical procedures were employed for their therapeutic effect and were not designed simply out of kindness or concern for the attendants' convenience. Broadly construed, "moral treatment" included all nonmedical techniques, but more specifically it referred to therapeutic efforts which affected the patient's psychology. Esquirol recognized this narrower definition: "Moral treatment is the application of the faculty of intelligence and of emotions in the treatment of mental alienation"(2).

The most famous symbol of this new therapy was the almost simultaneous unchaining of mental patients throughout Europe in the 1780's and 1790's. Humanitarianism was the major motivation behind this action, but some physicians, such as Pinel, released their patients partly to observe the natural course of the illness and, on the basis of increased knowledge, initiate more effective treatment.

"Moral treatment" consisted principally of what we might now call *milieu* therapy. Most doctors favored hospitalization for the severely ill patient. In order to break associations that were painful or that played a causal role in the illness, family and friends were usually prohibited from visiting the patient, as, of course, were the idly curious. Although patients were classified and separated according to sex, degree of illness, and socio-economic background, they all followed an orderly routine of life within the hospital. Distraction by work activity was increasingly recommended, as were amusements, which increased in number and variety over the years. The use of religious teaching varied from hospital to hospital, and the application of educational programs came only in the 19th century.

In the psychiatric literature of the time, one can also find a slight but growing discussion of how the doctor and his associates should deal with the patient. It is largely to those aspects of the doctor-patient transactions as they evolved between 1750 and 1840 and as they are presented by the out-

standing European and American psychiatrists of the time that this paper will be devoted.

DOCTOR-PATIENT RELATIONSHIPS

Perhaps the most significant feature of the doctor-patient relationship in these years was the gradual recognition by physicians that successful therapy required more active participation by the patient. The patient's attitude toward the asylum staff, especially the physician, received increasing attention. The ideal of what the patient's relationship with the physician should be gradually shifted from one in which the doctor was the active agent working upon an essentially passive subject to one where the patient became a partner, although a subordinate one, in the therapeutic process. For the patient to play an active role in his own treatment he must not be intimidated into passivity by the physician and other hospital personnel. Nor should he be treated as an anonymous member of a diagnostic category, but as an individual and interesting personality. Since incentives were essential to accomplishment of the desired change in the patient's attitude, systems of punishment and reward developed. This whole therapeutic process implied, moreover, a greater reliance upon the rational powers of the patient as a means of improving doctor-patient contact, and this reliance in turn stimulated an emphasis upon conversation, frank discussion, and general attempts by the doctor to re-educate the patient.

For the sake of simplicity and clarity, the following presentation will deal with the various stages as a logical progression, although, in fact, overlapping concepts and retrogressive tendencies were always present. Three essential themes are evident: 1. The nature of the doctor-patient relationship, 2. The development of self-control and the elimination of symptoms through reward and punishment and the use of emotions and reason, and 3. The practice of psychotherapy and its relationship to the patients' and doctors' personalities. Although this paper stresses the techniques used by physicians, it should be pointed out that in this period (1750-1840) lay superintendents and attendants frequently

played a more prominent role in nonmedical treatment than did the doctors. The material presented here represents only a small fraction of what was written, for most of the discussions on treatment were devoted to physical and pharmacological methods and to occupational and recreational therapy. The paper is based largely, moreover, on hospital experience.

As might be expected, especially in the years before 1800, one of the dominant themes in treatment was the need to gain ascendancy over the patient. In this way the patient could be led to control his behavior; such control seemed to be the first step towards cure, if not synonymous with it. At first there were traces of the former brutality. William Cullen(3) (1790) sanctioned the use of blows provided the patient understood their intent, and Benjamin Rush(4) (1812), citing a method of taming refractory horses in England, recommended that the patient be kept standing for an entire day.

These methods soon gave way to milder methods, with demonstrations of authority. A striking example was the approach used by Pargeter(5) in the 1790's, who thought treatment would be useless unless the physician gained supremacy in his first encounter with the patient. Suddenly flinging open the door of a patient's room, he would rush inside, catch the patient's eye, and thereby stare him down, so that he frequently achieved complete dominance without speaking a word. Pargeter claimed this technique had never failed him, but warned that it might not always work, and that therefore it was essential to obtain a case history before attempting to use this procedure. Once he had gained ascendancy he perpetuated it by treating the patient mildly and by attempting to win his confidence. He emphasized that too severe compulsion would be cruel and that it would arouse violent reactions in the patients and decrease their manageability.

Gradually such diverse physicians as Monroe(6) in 1758, Daquin(7) in 1791, Chiarugi(8) in 1793, and Pinel in 1801 came to suggest a less authoritarian approach. They emphasized that firmness should be tempered with kindness and that control was possible without abuse. Pinel

believed firmly in coercion where needed, but preferred the psychological effect of a show of force to its actual application.

After 1800 medical writers broadened the method of achieving dominance over the patient. Although Cox(9) in 1806 mentioned that some patients needed threats, he insisted that firmness and tenderness be the rule; he emphasized that kindness bred confidence, and that by releasing a patient from mechanical restraint the doctor might well win his devotion. In the same year Trotter(10) stressed the patient's need to sense the physician's trust in him. In 1809 Haslam(11) dismissed the effectiveness of the penetrating eye, stating that he had never found anyone willing to test this method on a furious maniac. He emphasized instead that patients tended to respect those who understood their complaint, and that therefore one could gain ascendancy through sympathy and understanding. He sanctioned the use of authority when needed, stating that one might act but should never threaten, and that setting an example was often effective.

In later years there was a shift to a relationship based on the subtleties of friendship and a consequent recognition of the value of tact in therapy. It was mentioned by Chiarugi in 1793 and by Heinroth(12) in 1818, and especially stressed by Burrows(13) in a perceptive account in 1828. In 1838 Ellis(14) proclaimed that women were superior to men in dealing with mental patients because of their greater tact.

With the emphasis on teaching the patient to control his own behavior, the question of reward and punishment inevitably arose. As early as 1795 Ferriar(15), who believed that a patient must minister to himself to achieve a cure, suggested setting aside a certain room for those convalescents whose behavior had become acceptable. Haslam suggested a few years later that the doctor should punish the rational but uncooperative patient by confining him to his room or forbidding him contact with other convalescents. He advocated immediate punishment, preferably ordered in front of other patients because, since the culprit tended to be awed by spectators, he would submit more readily. Haslam considered this type of coercion indispensable, since

self-control was essential for recovery and since fear of punishment deterred both the rational and irrational person.

This punitive technique was also used in the 1820's at the Friends' Asylum in Philadelphia(16); a patient's privileges would be curtailed for lack of self-control, but usually restored to him immediately if he evinced remorse for his behavior and promised to correct his errors. In 1833 Allen(17) emphasized the need to foster a patient's self-command by shaming him for misbehavior. He recognized that this course of action might encourage patients to conceal their illness, but felt that this situation was acceptable as long as the doctor was not deceived. Two years later Prichard(18) introduced the idea of making another person the agent of punishment and repression, so that the doctor could remain a protective figure, kind and indulgent.

Such emphasis on self-control signified training the patient to control his emotions, usually by exercising his will-power. Emotions aroused by the therapist might also help the patient; for example, in 1813 Samuel Tuke(19) cited the use of mild fear, as in the educational upbringing of children, but praised more highly the encouragement of such feelings as hope and self-esteem.

There was also a concept in therapy of the manipulation of emotions in another fashion. This method was often termed the use of "contrary passions" and was illustrated by Battie(20) in 1758, when he said that fear could be used to combat anger and that joy could dominate sorrow. But he warned that since it was difficult to predict results, only the doctor should decide whether this method was safe and advisable. In 1789 Harper(21) spoke out against any sudden check of the patient's passions, and instead recommended gradual replacement with other, more pleasant emotions. For example, the doctor should try to amuse the grief-stricken or depressed patient and should trust and console the jealous one. Pinel suggested providing pleasant surroundings and a cheerful atmosphere for the melancholic; his student Georget(22) thought that the doctor should try to impart courage to this type of patient. In 1803 Reil(23) proposed an early

form of psychodrama to arouse proper feelings in the patient.

A gradual shift to the use of milder emotions is evident in Cox's suggestion that other emotions besides fear be used, and in Allen's statement that if one must use fear one should do so only by removing sympathy. The doctors of the 1790's brought increased hope of cure to their patients, but it was only later that writers such as Trotter, Pisani(24), and Browne(25) emphasized the actual therapeutic value of hope.

Accepting the contemporary tripartite division of personality, Heinroth in 1818 advocated changing and stabilizing the emotions, giving direction to the will, and correcting the intellect. The writers before 1800 generally believed that these goals were seldom achieved by appealing to the patient's reason. Cullen pointed out that it was of little value in hypochondriasis, Perfect(26) made the same point regarding treatment of religious melancholy, and all physicians concurred in acknowledging the futility of reasoning or arguing with a patient about his delusional ideas. Of the various alternative methods which might serve to banish delusions and hallucinations, one of the most popular was a form of suggestive trickery termed "pious frauds" by Cullen and "strategems" by Pinel. The following is an example: a woman who thought she had snakes in her stomach was given an emetic; when she vomited, some real snakes were introduced into the basin and she was thereby convinced that she had finally expelled them. There were certain dangers in using this method, as Pinel recognized. He cites an initially successful strategem which was followed by a complete relapse when the patient learned it was a hoax.

After 1810, however, physicians came to frown on the use of strategems, agreeing that one should never deceive a psychiatric patient. They did continue to employ other types of suggestive therapy, as in the use of placebos by William Cullen and the superintendent of the Friends' Asylum. Interestingly enough, we have as yet found no direct evidence that the principles of mesmerism influenced the writers discussed.

Ideas about how to conduct what we

now call psychotherapy—the conversational transactions between the doctor and the patient—developed slowly. Beginning about 1790, there was increasing agreement that the doctor should know his patients individually and intimately by associating closely with them. Hahnemann(27) in 1792 spent two weeks studying a patient before embarking upon therapy. In 1793 Chiarugi requested referring doctors to provide case histories, and Pinel, Cox, and Heinroth also strove to obtain detailed records of their patients. Heinroth asserted that psychopathology would vary with age, sex and temperament, and that therefore therapy should vary accordingly. The individual personality was investigated more deeply by the phrenologists such as Combe(28) (1831) and Gall(29) (1825), who made the very perceptive suggestion that the physician might learn much by observing his patient's behavior and by encouraging him to talk about his past life.

The earlier psychiatrists were probably following association psychology when they stressed diverting the patient from his painful thoughts. This approach led to a therapy of distraction and repression which contributed to the widespread use of milieu therapy. Harper in 1789 suggested that ideas close to the original cause of the illness should not be mentioned or indulged, but that pleasant new ideas should be substituted for them. He also emphasized the necessity of breaking up habit patterns, but did not give any hints as to how this might best be done.

The doctors after 1790 recognized that conversation had certain beneficial effects. In 1795 Ferriar reported a cure that resulted from reflections initiated by a doctor's visit, and Allen mentioned a similar phenomenon much later. What Hallaran(30) in 1818 called "the business of conversation" was generally considered important, but the early physicians gave few rules about how to conduct this "business." In 1809 Haslam suggested that in order to learn more about the patient the doctor should not interrupt him too often, and most doctors agreed that one should avoid irritating the patient or bringing up painful ideas; for example, Burrows (1828) urged that defects in

memory or speech not be called to the patient's attention.
